Prevalence of Clinical Attachment Loss in Adolescents in Santo Domingo, Dominican Republic

James Collins,* Ana Maria Carpio,* Mónica Bobadilla,* Raysa Reyes,† Isabel Gúzman,‡ Benjamin Martínez,§ and Jorge Gamonal†

Background: Data on periodontal conditions in adolescents in the Dominican Republic are scarce. The aim of the present cross-sectional study was to estimate the prevalence of periodontal attachment loss among Dominican adolescents. This study did not attempt to classify the disease into aggressive and chronic periodontitis.

Methods: A random sample of 2,007 Dominican adolescents was obtained. A probability, weighted sample was selected using a complex, multi-stage probability sampling design. The study was clustered in 26 schools and 106 classes. The study subjects were clinically examined under field conditions by a single calibrated examiner who measured gingival recession and probing depth at six sites per tooth, with subsequent calculation of clinical periodontal attachment level for each site.

Results: The prevalence of clinical attachment loss ≥1 mm was 49.5%, with the prevalence ranging between 48.7% and 50.2%, depending on age and gender. Clinical attachment loss ≥2 mm was found in 15% of the students and attachment loss ≥3 mm in 4.0% of the students. Logistic regression model revealed that only age significantly increased the probability of having clinical attachment loss.

Conclusion: We conclude that clinical attachment loss is common in adolescents in Santo Domingo, Dominican Republic, suggesting the necessity for improved standards of prevention, diagnosis, and treatment of these lesions. J Periodontol 2005;76:1450-1454.

not attempt to classify the disease into aggressive and chronic periodontitis.

**MATERIALS AND METHODS**

**Study Population**

The study sample was calculated according to the method described by Cochran\(^4\) at 95% confidence interval with a 0.02% range of error and consisted of 2,007 adolescents. The prevalence of clinical attachment loss described by López et al.\(^5\) was used to determine the sample size. The students in the study were selected using a multi-staged probability sample covering the high schools of Santo Domingo, Dominican Republic. School districts (primary sampling units) and school (second stage) were drawn from a national list of school districts and schools. The sampling units were weighted based on the selection probability and the weights were adjusted using data on the primary sampling units, school district, and the sampling unit. The third stage included selecting classes within each school from a list of classes by grade level. All students within the sampled classroom were candidates for examination. The study protocol was approved by the local Committee of Ethics of Catholic University, Santo Domingo, Dominican Republic and participating students gave their consent.

**Examinations**

Clinical attachment loss (CAL) was used to record periodontal conditions. The examination was carried out by a single well-trained and calibrated examiner (JC). On successive days, groups of 20 subjects were examined who had the full range of periodontal conditions expected to be assessed during the survey. Examinations (probing) were repeated until acceptable consistency was achieved (kappa = 0.61 and 0.80, considered to be good to excellent).\(^6\) The examinations were carried out using headlamps, dental mirrors, and calibrated manual periodontal probes (tip diameter 0.5 mm). Assesment of the periodontal supporting tissues status was made by clinical measurement of the distance from the cemento-enamel junction (CEJ) to the free gingival margin (FGM), and the distance from the FGM to the bottom of pocket/sulcus. From these two measurements, the periodontal attachment loss (distance from the CEJ to bottom of pocket/sulcus) was calculated. Six sites (mesio-buccal, mid-buccal, disto-buccal, mesio-lingual/mesio-palatal, mid-lingual/mid-palatal, and disto-lingual/disto-palatal) of all first and second molars and all incisors present were examined.\(^5\) All measurements were rounded down to the nearest whole millimeter.

**Statistical Analysis**

Logistic regression models were used to assess the influence of the variables age, gender, and smoking on at least two teeth with CAL \(\geq\) 1 mm or at least one tooth with CAL \(\geq\) 3 mm. As clinical attachment loss in buccal sites might not be the result of an inflammatory disease process, but could result from traumatic injuries induced, for instance, by vigorous tooth brushing we repeated the above logistic regression analyses using the occurrence of at least two teeth with CAL loss \(\geq\) 1 mm in interproximal sites, or at least one tooth with CAL \(\geq\) 3 mm in interproximal sites.\(^5\) Risk ratios were calculated with 95% confidence intervals (CI). Statistical significance was defined as \(P < 0.05\).

**RESULTS**

A total of 2,007 students from 106 classes in 26 high schools were included in the study. Forty-four had no clinical attachment loss and were excluded from the study. Table 1 shows the distribution of the sample by age and gender. Overall, 49.5% of the students examined had at least one site with clinical attachment loss \(\geq\) 1 mm, with prevalence ranging between 48.7% and 50.2%, depending on age and gender. CAL was \(\geq\) 2 mm in 15% and \(\geq\) 3 mm in 4.0% of the students.

More males than females were affected \((P < 0.05)\) and prevalence was higher in students aged 18 to 21 \((P < 0.05)\) (Table 1). The proportion of subjects with clinical attachment loss \(\geq\) 2 mm and \(\geq\) 3 mm was also higher in adolescents aged 18 to 21 \((P < 0.05)\).

Table 2 shows the prevalence of CAL in interproximal sites by age and gender and the mean number of sites affected. Sites with CAL \(\geq\) 1 mm were seen in 33.6% of the students, with the prevalence ranging between 29.1% and 34.9%, depending on age and gender. The prevalence of CAL \(\geq\) 2 mm and \(\geq\) 3 mm was seen in 10.9% and 3.5% of the students, respectively. The percentage of students with \(\geq\) 3 mm attachment loss increased with age from 2.4% in the 12 to 14 year old group to 4.1% in the 18 to 21 year group \((P < 0.005)\).

Logistic regression model was constructed to analyze the variables associated with higher probability of clinical attachment loss: age, gender, medication, smoking, and no dentist visit in the past year. Only age significantly increased the probability of having clinical attachment loss (odds ratio = 1.56; CI 1.02 to 2.24).

**DISCUSSION**

This survey has provided valuable data concerning adolescent periodontal status in the Dominican Republic. Although the adolescent surveyed in the present study do not represent the total adolescent Dominican population aged 14 to 21, the sample does represent this age group in Santo Domingo. The prevalence of CAL \(\geq\) 1 mm in Dominican adolescents was 49.5%; \(\geq\) 2 mm, 15%; and \(\geq\) 3 mm, 4.0% of the students. Detailed information on the prevalence of clinical attachment loss...

among adolescents is useful for two reasons. First, because most of the research effort in periodontal epidemiology has focused on middle-aged or older people. Second, understanding the epidemiology and clinical presentation earlier in the course of the disease may enable more timely and appropriate interventions in both the clinical and population levels to reduce the incidence and prevalence of periodontal loss of attachment.7

It should be noted, however, that it is not always feasible to compare the prevalence of disease reported by different studies due to differences in sampling and study design and the different classifications and diagnostic criteria for the disease.8 Clinical measurements of periodontal attachment loss and/or radiographic assessment of alveolar bone loss at a given point time and/or longitudinally, as well as the age of onset of disease, are key parameters currently used for the identification and classification of cases. Most studies have used clinical and/or radiographical methods to assess the presence of periodontal tissue loss, customarily using a threshold of ≥3 mm to define periodontal tissues loss, although lower and higher thresholds have also been used. This lack of consistency undoubtedly is an important factor causing, at least in part, some of the differences in the occurrence of disease in different studies.9 Gjermo et al.10 used a convenience sample of 304 children, 15 years old, from a public school in a low socioeconomic area who were examined by bite-wing radiographies. Twenty-eight percent of the children had radiographic bone loss, and 2.6% were diagnosed as having aggressive periodontitis. Albandar et al.11 studied 222 children aged 13 years from a private school in a relatively high socio-economic area in Sao Paulo using a similar examination method to that used by Gjermo et al.10 They found that 5.4% of the subjects had vertical bone loss at one or more sites. Aggressive periodontitis, defined as vertical or arc-shaped bone loss on ≥2 first molars, was diagnosed in 1.3% of the children. Lopez et al.12 studied the prevalence of aggressive periodontitis among students aged 15 to 19 years using a random sample of children representative of different socio-economic strata and ethnic groups in Santiago. In this study, children who had two or more teeth with >5.5 mm probing depth were invited for a radiographic examination consisting of bite-wing radiographs of first molars and periapical radiographs of incisors. The overall prevalence of aggressive periodontitis was 0.32%. A much higher prevalence was found in females than in males (7:1), and in subjects with a low socioeconomic level.

The prevalence of clinical attachment loss ≥1 mm observed in the present study is lower than that observed among a population of Chilean adolescents, but similar at CAL ≥2 mm. Lopez et al.5 described a large survey conducted in 1999 that used a multi-stage probability design to select 9,162 students, 12 to 21 years old, representative of high school students in the province of Santiago, Chile. They found that 4.5% of all students examined had clinical attachment loss of ≥3 mm: 3% in 12 to 14 years old, 4.5% in 15 to 17 years old, and 8.2 in 18 to 21 years old. Females had a slightly higher prevalence of disease than males (4.9% versus 4%). When attachment loss was assessed on the interproximal surfaces only, a slightly lower prevalence was reported (total: 3.7%; 12 to 14 years: 2.5%; 15 to 17 years: 3.7%; 18 to 21 years: 6.8%; females: 4.1%, males: 3.3%). The prevalence of clinical attachment loss ≥3 mm observed in the present study is higher than observed among Danish school children,13 lower than observed among U.S. African-American school children,14 and similar to that observed among Chilean adolescents.5

A wide range of demographic factors, such as age, gender, place of residence, educational level, and socio-economic factors, have been identified as associated with chronic inflammatory diseases.15-17 Age, gender, tobacco use, and diabetes mellitus have been consistently identified as important potential risk factors for destructive periodontitis.18-20

In the current study, the prevalence of clinical attachment loss increased with age, as has been found in many studies. Most epidemiological studies showed that periodontal disease is more severe in elderly people because of cumulative tissue destruction rather than an age-related intrinsic abnormality.19,21-22

This current study provides the first published detailed data describing the periodontal status in Dominican adolescents attending school and suggests this population has a relatively high prevalence of clinical attachment loss. The main emphasis should be on the application of preventive measures in school children, teenagers, and young adults so they can reach older age periodontally healthier than the current generations.
