Solid-organ transplant recipients rely on pharmacological immunosuppression to prevent allograft rejection. The effect of such chronic immunosuppression on the microflora at mucosal surfaces is not known. We evaluated the salivary bacterial microbiome of 20 transplant recipients and 19 nonimmunosuppressed controls via 454 pyrosequencing of 16S rRNA gene amplicons. Alpha-diversity and global community structure did not differ between transplant and control subjects. However, principal coordinate analysis showed differences in community membership. Taxa more prevalent in transplant subjects included operational taxonomic units (OTUs) of potentially opportunistic Gammaproteobacteria such as Klebsiella pneumoniae, Pseudomonas fluorescens, Acinetobacter species, Vibrio species, Enterobacteriaceae species, and the genera Acinetobacter and Klebsiella. Transplant subjects also had increased proportions of Pseudomonas aeruginosa, Acinetobacter species, Enterobacteriaceae species, and Enterococcus faecalis, among other OTUs, while genera with increased proportions included Klebsiella, Acinetobacter, Staphylococcus, and Enterococcus. Furthermore, in transplant subjects, the dose of the immunosuppressant prednisone positively correlated with bacterial richness, while prednisone and mycophenolate mofetil doses positively correlated with the prevalence and proportions of transplant-associated taxa. Correlation network analysis of OTU relative abundance revealed a cluster containing potentially opportunistic pathogens as transplant associated. This cluster positively correlated with serum levels of C-reactive protein, suggesting a link between the resident flora at mucosal compartments and systemic inflammation. Network connectivity analysis revealed opportunistic pathogens as highly connected to each other and to common oral commensals, pointing to bacterial interactions that may influence colonization. This work demonstrates that immunosuppression aimed at limiting T-cell-mediated responses creates a more permissive oral environment for potentially opportunistic pathogens without affecting other members of the salivary bacteriome.

The advent of rRNA gene-based taxonomic identification combined with high-throughput sequencing technologies permits comprehensive characterization of the host microflora, providing a view of microbiome diversity not previously possible. This molecular approach allows evaluation of global microbial profiles, overcoming the limitations of cultivation, which reveals only 30 to 80% of the flora present at host sites (7, 8). High-throughput sequencing of rRNA gene libraries has never been used to evaluate the effect of long-term immunosuppression on the microbial communities that reside at mucosal surfaces. In a prior cultivation-based comparison of the frequency of oral carriage of Candida spp. in solid-organ transplant recipients and nonimmunosuppressed individuals, our group reported that the frequency of carriage of non-albicans Candida spp. is higher in transplanted subjects (9). In the present study, we evaluated the oral bacterial microbiome of a subgroup of these immunosuppressed individuals and compared their salivary bacteriomes to those of nonimmunosuppressed controls. Our objective was to define the alterations inflicted on the resident oral bacterial flora by chronic pharmacological immunosuppression.

**MATERIALS AND METHODS**

**Studied populations, medical data collection, and sampling.** The population investigated was a subset from a larger study that recruited 90 renal and cardiac transplant recipients and 72 controls (9, 10). All study procedures were approved by the Institutional Review Boards from the University of Connecticut Health Center and Hartford Hospital. The current study included 20 subjects from the transplant group and 19 from the control group. Subjects were selected based on availability of saliva samples for microbial profiling. Transplant subjects met the following inclusion criteria: (i) at least 1 year posttransplant; (ii) clinically stable, as defined by serum creatinine levels (kidney only) and no signs of recurrent primary disease or acute rejection; and (iii) no history of antibiotic, antifungal, or antiviral usage during the previous 4 months. Control subjects had no immunological compromising condition and no history of antibiotic, antifungal, or antiviral usage during the previous 4 months.

Medical records of transplant subjects were reviewed, and all relevant information was collected using a standardized data extraction form, as previously described (10). A self-reported medical history was obtained from control subjects. Serum values of C-reactive protein (CRP) and interleukin-6 (IL-6) were determined in both groups via enzyme-linked immunosorbent assays. Descriptive statistics on the entire study population were previously reported (10).

Subjects also received a comprehensive oral examination, which included determination of the number of missing teeth (excluding third molars), plaque scores (% of surfaces positive for plaque), evaluation of periodontal health, and evaluation of mucosal disease. Unstimulated whole saliva and swabs from the oral mucosa were collected as previously described (9). Determinations of Candida load in saliva and oral mucosa and Candida species identification were performed via cultivation methods as previously reported (9).

**DNA isolation from saliva, 16S rRNA gene library preparation, and sequencing.** DNA was isolated from whole unstimulated saliva according to previously described procedures using lysozyme and proteinase K treatments and a DNeasy blood and tissue kit (Qiagen) (11). Amplicon libraries of 16S rRNA gene V1-V2 hypervariable regions were generated in triplicate using fusion primers, which included universal primers 5′-GAGTTTGTATCTGGCTACGG3′ and 361R (5′-CYACTGCTGCTCCCTCCTAAGAG3′) (12), Roche Life Sciences’ 454 Lib-A adapters A and B, and a unique multiplex identifier. PCR and library preparation procedures have been described previously (11). Briefly, PCR mixtures contained 10 ng of purified DNA, 1 U platinum Taq polymerase (Invitrogen), 1.5 mM MgCl₂, 200 μM deoxyribonucleotide triphosphates (dNTPs), Taq buffer (1X), 0.5 μM each forward and reverse primer, and molecular-grade water to a final volume of 25 μL. Thermal cycler conditions were initial denaturation at 95°C for 3 min; 25 cycles of denaturation at 95°C for 30 s, annealing at 50°C for 30 s, and extension at 72°C for 1 min; and a final extension step at 72°C for 9 min. Negative controls included a DNA isolation control and a PCR control with no added template. Combined triplicate amplicon libraries were sequenced in the forward direction using 454 Titanium chemistry on the 454 GS-FLX platform (454 Life Sciences). Sequences are available at the Short Reads Archive (accession number SRA062231).

**Sequencing data processing.** Sequence data were processed using a modification of the pipeline by Schloss et al. (13), as previously described (11), using mothur (14). For operational taxonomic unit (OTU)-based analysis, sequences were clustered using the average neighbor algorithm (15) and a 3% dissimilarity cutoff. Template taxonomies included the large ribosomal database project (RDP) reference data set and the Human Oral Microbiome Database (HOMD), a curated data set, including a large collection of species-level taxa from the oral cavity previously identified (16). OTUs were assigned a taxonomy based on the consensus taxonomic assignment for the majority of sequences within each OTU. If a consensus taxonomy was not possible at the species level (based on HOMD), the nearest taxonomical level at which a consensus was reached was reported. In such cases, the representative sequence from the OTU was also compared to the HOMD, and if results showed more than 97% similarity to an oral taxon (OT), the OT name of the top hit was reported in parentheses as part of the OTU taxonomy. Individually classified sequences were also grouped into phylotypes (from genus to phylum level) based on taxonomic identity.

Sequence libraries were subsampled to contain the same number of sequences for α-diversity comparisons. Richness was evaluated by the number of observed OTUs and number of estimated OTUs as calculated with CatchAll (17). Diversity was measured by the nonparametric Shannon index (18) and the inverse of the Simpson index (19). β-Diversity was measured with the Jaccard index for comparison of communities based on membership and the βPCoA distance (20) for comparison of communities according to their structure. Principal coordinate analysis (PCoA) of the distance among communities based on the Jaccard and βPCoA metrics was performed in mothur, and graphs were visualized using the rgl application within R (http://www.r-project.org/). Methods used for DNA isolation, amplicon library preparation, sequencing, and microbial profile analysis have been previously validated using a mock community of oral microorganisms (11).

**Statistical analysis.** Clinical and demographic data were compared via t tests, chi-square tests, or Mann-Whitney tests, as appropriate. Differences in α-diversity were evaluated by t tests. Significant separation of clusters after PCoA was evaluated via analysis of molecular variance (AMOVA) (21), as implemented in mothur. Differences in relative abundances of individual OTUs and genera were determined via Metastats (22), while differences in taxa prevalence were tested via chi-square test. While all genera were included in these analyses, only OTUs with 10 or more sequences were considered for relative abundance and prevalence comparisons. Bivariate correlations between taxon-relative abundance, taxon prevalence, Candida-related variables, diversity measures, and dose of immunosuppressants were performed via Spearman rank order correlation tests. Prior to correlations, OTU and genus-relative abundances were transformed using the inverse hyperbolic sine method (23). The significance threshold for statistical tests was adjusted using the Benjamini-Hochberg false discovery rate method.

To facilitate interpretation of prevalence data, we used the Chernoff bound to calculate the minimal relative abundance for which we could have 95% certainty that we will observe at least one sequence at our sequencing effort (see Methods in the supplemental material).

OTU relative abundance data were used to perform correlation network analysis, which identifies clusters (modules) of highly correlated OTUs. Weighted correlation network analysis (WGCNA) (24) was performed as previously described (25). Nodes in undirected weighted net-

works represented OTUs, and edges represented their adjacency. We first identified outlier samples using absolute hierarchical cluster analysis and constructed a weighted network choosing a soft thresholding power β of 4 with an R2 value of 0.85. Network data were visualized in Cytoscape (26) using the weighted force-directed layout algorithm, with edge length representing the adjacency between nodes. Network centrality measures for the modules obtained were assessed using Cytoscape (26). To relate modules to clinical variables (traits), we also used the WGCNA package containing the adjacency between nodes. Network centrality measures for the modules obtained were assessed using Cytoscape (26). To relate modules to clinical variables (traits), we also used the WGCNA package containing the adjacency between nodes.

RESULTS

Demographic and clinical characteristics of subjects included in this study. Table 1 shows the demographic and clinical information of transplant and control subjects. The two groups did not differ in terms of their age, gender, and body mass index (BMI). The transplant group, however, included more diabetics than the control group. In agreement with our previous findings pertaining to the entire study population (10), the transplant recipient subset included in this study showed significantly higher levels of serum CRP and IL-6 than the controls. Parameters related to oral health did not differ between the two groups.

Assessment of oral colonization by Candida spp. in the transplant and control groups via culturing methods showed no differences in the presence and load of Candida albicans or in the total Candida species load. However, as previously reported by the parent study (9), there was a greater number of non-albicans species from the genus Candida present in saliva and oral mucosal of transplant subjects than in the controls. This difference, however, did not reach statistical significance in this cohort (Table 1).

In the transplant group, 19 subjects had received a kidney transplant, while 1 subject was a heart recipient. The average number of years posttransplant was 5.2 ± 4.2 (range of 2 to 16 years), with 45% of subjects having received a transplant from a living donor and 40% of subjects with a history of rejection. Subjects were taking multiple combinations of medications as part of their immunosuppressive regimens, with 90% of subjects on prednisone, 80% on mycophenolate mofetil, 65% on tacrolimus, 35% on cyclosporine, 15% on sirolimus, and 10% on azathioprine. In addition, 30% of subjects were taking calcium channel blockers.

Transplant status does not influence the diversity and global structure of salivary bacterial communities but affects community membership. A total of 183,398 raw sequence reads were obtained, of which 152,301, with an average read length of 222 bp, were included in the final analysis. The range of sequence reads obtained per subject varied from 1,709 to 7,725; thus, for α- and β-diversity comparisons, all subject libraries were randomly subsampled to contain 1,709 reads.

A total of 642 OTUs were observed across all subjects after subsampling; however, the average number of observed OTUs per subject ranged from 59 to 178, indicating intersubject variability in the salivary microbiome at this sequencing effort. Calculations of the number of OTUs predicted to exist in each subject using CatchAll (17) revealed a range of estimated OTUs per subject of 70 to 262. Figure S1 in the supplemental material depicts comparisons of α-diversity between transplant and control subjects.

Panel B shows that richness (both observed and estimated OTUs) did not differ between groups, while panel B demonstrates that diversity did not vary between transplant and control subjects.

Next, we evaluated overall differences in community composition and in community structure between transplant and control groups. Figure 1 shows PCoA plots of distance among communities according to OTU-based Jaccard (Fig. 1A) and βc
Communities of transplant and control subjects did not form completely separate clusters in these plots. However, comparison of community membership shows that despite some overlap, the two data clouds were statistically different from each other (AMOVA \( P = 0.006 \)). These observations indicate that transplant status does partially influence community membership (presence/absence of species) but does not affect community structure (the distribution of species counts, i.e., relative abundance). Since transplant and control subjects differed in the number of diabetic subjects and in their serum CRP and IL-6 levels, we also evaluated if these variables were related to community membership and could have confounded the differences observed. As Fig. 1C, D, and E indicate, diabetes, CRP, and IL-6 were not drivers of community composition, further confirming that the observed differences were due to transplant status. Similarly, Fig. 1F shows that the presence of periodontitis did not explain the organization of data points in the Jaccard-based PCoA plot. Furthermore, BMI and other oral health parameters depicted in Table 1 were not found to be drivers of salivary community membership or structure (data not shown).

Differences in prevalence of individual taxa between transplant and control groups were then evaluated. We found 17 OTUs and 3 genera with significantly different prevalence between groups (Fig. 2). None of these taxa, however, were among the most fre-
quent detected taxa in salivary communities (depicted in Fig. S2A and S3A in the supplemental material). Among the microorganisms with increased prevalence in transplant subjects (Fig. 2) were Gammaproteobacteria such as Klebsiella pneumoniae, Acinetobacter sp. OT408, which is a close phylogenetic relative of Acinetobacter baumannii, and Pseudomonas fluorescens, all of which are frequently associated with extraoral infections in immunocompromised patients (4, 27, 28). The periodontal pathogen Treponema denticola was also more frequently found in the transplant population, although both groups did not differ in terms of their periodontal health (Table 1). Interestingly, control subjects showed increased prevalence of an OTU of Pseudomonas sp. closely related to Pseudomonas stutzeri, a Pseudomonas sp. very rarely seen as a human pathogen (29).

Differences in relative abundance of individual taxa were also evaluated. The B panels in Fig. S2 and S3 in the supplemental material show the most abundant OTUs and genera in transplant and control subjects. Salivary communities were dominated by Streptococcus spp. comprising about 25% of sequence reads, followed by Prevotella spp., Veillonella spp., uncultured TM7 G-1 and Fusobacterium spp., all found at 5 to 10% abundance. Figure 3A shows OTUs differentially represented in terms of their relative abundance in each group. In agreement with prevalence data, we found Gammaproteobacteria such as Pseudomonas aeruginosa, an Acinetobacter sp., and an Enterobacteriaceae sp. closely related to Enterobacter cancerogenus increased in transplant subjects. In addition, Enterococcus faecalis, an organism associated with infections in immunocompromised hosts (30), was increased in the transplant group. In Fig. 3B, genera with different relative abundance between groups are depicted. Among these, we found of interest that the genus Staphylococcus, commonly associated with extraoral infections in immunosuppressed populations (3), was increased in the transplant group.

Relationship between dose of immunosuppressants and the prevalence and relative abundance of individual oral taxa. A bivariate correlation analysis was performed to evaluate whether exposure to immunosuppressants was associated in a dose-dependent manner with the prevalence or relative abundance of transplant-associated OTUs and genera. The relationship between fungal colonization as determined by culturing methods (9) and immunosuppressant doses was also evaluated. From all the individual immunosuppressant drugs subjects were receiving, only prednisone and mycophenolate mofetil were significantly associated with microbial colonization of the oral cavity (Table 2). Prednisone dose showed a positive correlation with both the relative abundance and prevalence of 2 OTUs, identified as an unclassified Enterobacteriaceae species and a Vibrio species, and with the genera Klebsiella and Acinetobacter. The dose of mycophenolate mofetil also correlated with some of the bacterial variables evaluated, showing a positive correlation with the relative abundance of the genera Staphylococcus, Acinetobacter, and Klebsiella and with the prevalence of Klebsiella. Interestingly, the dose of prednisone and not that of mycophenolate mofetil showed a positive correlation with OTU richness, an indication that prednisone-related systemic immunosuppression is associated with a more permissive oral environment, conducive to increased bacterial diversity. In contrast, mycophenolate mofetil, and not prednisone, showed a positive correlation with the load and number of Candida spp. in the oral mucosa, which suggests that mycophenolate mofetil-related immunosuppression exerts a stronger influence on fungal colonization than prednisone.

We also tested if transplant-associated OTUs and genera (Fig. 2 and 3) correlated with indicators of transplant function (history of rejection, fibrosis, inflammatory changes) or other transplant-related variables (posttransplant years, live or cadaveric donor), but no significant correlations were found (data not shown).
To test if local factors related to oral health could be associated with increased colonization by opportunistic pathogens, a correlation analysis of oral health variables and prevalence or relative abundance of transplant-associated OTUs and genera was performed. No correlations were found, however, between oral health indicators and carriage of these bacterial taxa. Interestingly, in this analysis, salivary carriage of taxa classically associated with periodontitis, such as *T. denticola*, did not show a positive correlation with specific periodontal health-related parameters. Since we had reported a positive correlation between the prevalence of *T. denticola* and prednisone dose (Table 2), we also tested if prednisone dose correlated with oral health parameters but found no correlation. With respect to fungal colonization, we found that the number of *Candida* spp. in mucosa positively correlated with...

\(c\) Data correspond to OTU richness measures per sample. Total richness \(\text{(estimated OTUs)}\) was determined with CatchAll \((17)\).

\(d\) Candida spp. colonization was measured as total CFUs recovered from a single mucosal swab.

Correlations among salivary bacterial OTUs and the relationship of these networks to transplant status. Next, we used WGNCA to find modules of salivary OTUs highly correlated to each other in their trend of frequency distributions. Figure S4 in the supplemental material shows the initial hierarchical clustering of samples. Eight modules of closely correlated OTUs were found (see Fig. S5 in the supplemental material), which were arbitrarily assigned to a color for their identification. Figure 4 shows the correlation of each module with subject demographic characteristics, transplant status, and levels of serum inflammatory markers. As seen in Fig. 4A, the brown module was the only one showing a positive correlation with transplant status. Interestingly, this module also showed a positive correlation with serum levels of CRP, a marker of systemic inflammation. Figure 4B shows the OTUs that form the brown module and their connections. In accordance with analysis of individual taxa, the brown module contained OTUs shown to be increased in transplant subjects or OTUs from genera individually associated with the transplant group (as per Fig. 2 and 3) and representing potentially opportunistic pathogens. The brown module also contained OTUs highly prevalent and abundant in salivary bacterial communities (as per Fig. S2 in the supplemental material) and considered to be prime oral commensals, such as *Streptococcus* sp. (*S. parasanguinis* II OT411), *Streptococcus* sp. (*S. infantis* OT638), *Granulicatella adiacens*, *Oribacterium* sp. OT108, and *Actinomyces* sp. (OT172). An uncultured *Clostridiales* sp., very abundant in saliva, was also part of this network. The relationship of OTUs within this network was further explored by measuring degree centrality (number of connections a node has). It was found that transplant-associated opportunistic pathogens displayed the highest degree centrality. These results are displayed in Fig. 4B and indicate that relative abundances among opportunistic species appeared to be highly correlated, while these microorganisms also interact closely with all commensals and nonhub microorganisms in the network.

Figure S6 in the supplemental material shows the black module, which was found to be negatively associated with transplant status. This network contained taxa seen in individual analysis as associated with control subjects. Interestingly, *Pseudomonas* spp. with low pathogenic potential in humans were part of this cluster.

DISCUSSION

We have conducted the first comprehensive evaluation of the effect of long-term transplantation-related immunosuppression on the oral bacterial microbiome. Previous studies that evaluated the oral microflora in organ recipients suffered from the limitations of using a cultivation approach, which allowed identification of only a small number of species, and were confounded by the effects of antibiotics on the microflora of the studied subjects \((31,32)\). Using high-throughput sequencing of 16S rRNA gene libraries, we found that pharmacological immunosuppression aimed at increasing allograft tolerance does not affect the most common and abundant bacterial species in saliva but increases the frequency of detection of microorganisms known to be the cause of extraoral infections in transplant recipients \((4,27,30)\). Oral colonization by Gram-negative rods such as *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, *Pseudomonas fluorescens*, and Acinetobacter baumannii and by Gram-positive cocci such as *Staphylococcus aureus* and *Enterococcus faecalis* has been previously noted in other medically compromised subjects, particularly in bed-ridden elderly individuals \((33)\). Although it could be suspected that these pathogens colonize hospitalized elderly populations more frequently because of their compromised immunological responses, most studies attributed their increased frequency of detection to local factors, such as deficient salivary flow, lack of adequate oral hygiene, or antibiotic use, which are thought to disrupt the resident commensal flora \((33)\). Subjects in our study, however, had not taken any type of antimicrobial for 4 months prior to sampling and did not have oral health or hygiene (plaque score) different from that of control individuals. Moreover, we found no correlation between the prevalence and relative abundance of transplant-associated OTUs and genera from potentially opportunistic pathogens and oral health parameters. Thus, the differences found can be directly attributed to the effect of immunosuppressive regimens on oral colonization.

Traditionally, *Klebsiella* spp., *Acinetobacter* spp., *Pseudomonas* spp., and staphylococci are not considered to form part of the regular oral commensal flora during health \((33)\), although several studies using cultivation methods have revealed their presence in the oropharynx of a minority of subjects \((34,35)\). Our study agrees with the latter studies in finding these opportunistic pathogens in...
FIG 4  Network correlation analysis identified a cluster (brown) associated with transplant status and containing OTUs from potentially opportunistic pathogens. Panel A shows correlations between demographic and clinical subject characteristics and the 8 different salivary OTU clusters identified in all subjects (transplant and control). Correlations are color coded, with red indicating the highest positive correlation and green the lowest negative correlation. Coefficients and P values appear in parenthesis. Panel B shows the OTUs that comprise the brown cluster and their connections. Each node in the network represents an OTU. Edge length represents adjacency between pairs of nodes. OTUs that were identified as transplant associated in individual taxa analysis are shown in yellow. Size of each node represents OTU connectivity, measured as degree centrality (number of connections with other nodes), with the bigger nodes representing those highly connected.
a small number of samples in the control group. These results are also in agreement with a recent analysis of data from the Human Microbiome Project, which found *S. aureus*, *K. pneumoniae*, and *E. faecalis* at very low prevalence and in low proportions (~0.01% to 0.1% of the total flora) in saliva samples of healthy individuals (36). However, when interpreting prevalence data, it should be considered that lack of detection of a taxon in a given sample depends on its relative abundance and on sampling effort. Richness coverage in our study ranged from 54% to 87% of the OTUs predicted to exist in individual samples by the CatchAll estimator, indicating that a portion of the flora was not observed. By using the Chernoff bound, we calculated that at a sequencing effort of 1,709 sequences, 0.0052% is the lowest relative abundance at which a species could exist in a sample and be detected with 95% confidence. Therefore, opportunistic pathogens could have been part of the regular oral commensal flora of a greater number of individuals from the control group but present in very low abundance (less than 0.0052%) and therefore not detectable by our depth of sequencing. Thus, the increased frequency of detection of opportunistic pathogens in transplant subjects could reflect higher relative abundance than in controls, and it is not necessarily a consequence of differences in carriage. It should also be taken into account that the lysis method used for this study has been validated only for oral taxa (11). Some of the opportunistic species detected require special lysis protocols, and they may be underrepresented in our samples. It is then quite possible that opportunistic pathogens are common low-abundance inhabitants of the oral cavity in health. This question can be answered in future studies by utilizing a deeper sequencing approach and targeted lysis methods. The increased detection and higher proportions of opportunistic pathogens in transplant recipients is, however, an indication that systemic immune defenses serve as gatekeepers for opportunistic pathogens in transplant recipients and therefore the correlation of opportunistic pathogens with transplant status. This analysis revealed that the individual doses of two agents, prednisone and mycophenolate mofetil, showed the strongest correlations with prevalence and abundance of individual taxa. These results are possibly due to an independent effect of each agent on the oral microbiome. We found, for example, that although the dose of both agents correlated with some of the transplant-associated bacterial taxa, prednisone showed a higher number of significant correlations than mycophenolate mofetil. Moreover, prednisone, and not mycophenolate mofetil, correlated with bacterial richness, a suggestion that prednisone has a more profound effect on oral bacterial colonization. It is difficult to pinpoint, however, the mechanisms behind the apparently more permissive oral environment for bacteria created by prednisone, as this drug has a wide range of effects on immune responses (38). In contrast, we found that the dose of mycophenolate mofetil (and not that of prednisone) correlated with *Candida* species load and diversity in the oral mucosa. It is worth noting that no correlation was found when *C. albicans* loads alone were considered, a result that indicates that mycophenolate mofetil may create a more permissive environment only for non-*albicans Candida* spp. Mycophenolate mofetil has a somewhat narrow effect on host cells, specifically targeting activated T and B lymphocytes (39). It is then possible that non-*albicans Candida* spp. are more deeply affected by these altered acquired immune responses than the bacterial flora.

Network correlation analysis also confirmed the association between opportunistic pathogens and transplant status. This analysis revealed that opportunistic pathogens tend to cooccur in the same subjects. Not all transplant subjects, however, were colonized by opportunistic pathogens, and therefore the correlation of the brown module and transplant status was only weakly significant. It is also worth noting that due to the limited sample size, the relationships uncovered are preliminary. It was interesting to observe, however, that potential opportunistic pathogens are not only associated with each other but also connected to common and abundant oral commensals. These findings suggest that the ability of potential opportunistic pathogens to colonize oral surfaces not only depends on decreased immune surveillance, but it may also be facilitated by certain members of the commensal flora.

Although not the main purpose of this study, our evaluation of the salivary microbiome in this cohort of 39 subjects provides...
further confirmation of the microorganisms that reside in human saliva. Our results mostly agree with those from published 16S rRNA gene-based characterizations of the salivary bacterial flora (40–42), showing that despite the inclusion of different populations and utilization of various sampling methods, primers, and sequencing strategies, a concordant picture is emerging on the salivary bacteriome. For example, Segata et al. (40) reported that Streptococcus, Veillonella, and Prevotella are the most abundant genera in saliva, in agreement with our results. Our analysis, however, utilizes the HOMD (16), a curated data set for oral taxa, which allows identification of most OTUs at a species level and permits to assign traceable sequence identities to uncultured taxa. For instance, in the case of uncultured TM7, our analysis allowed to ascertain the identity of the most abundant TM7 in saliva as TM7 genospecies 1 (according to the HOMD phylogenetic classification).

In conclusion, this study evaluated the salivary microbiome of solid-organ transplant recipients, finding that immunosuppression does not exert a significant effect on the most abundant bacterial taxa but increases the frequency of detection and relative abundance of taxa documented to behave as opportunistic pathogens in immunocompromised hosts. Among the immunosuppressant agents subjects received, prednisone had the most significant effect on bacterial diversity and on the colonization of potential opportunistic pathogens, while mycophenolate mofetil had a more limited effect on the bacterial flora but was associated with increased colonization by non-albicans Candida spp. Further studies should clarify the specific mechanisms mediating the effects of these pharmacological agents at oral mucosal surfaces and the association between an increase in the nonsymptomatic carriage of opportunistic pathogens at mucosal sites and risk for distal infections in transplant recipients.
