OPTIMAL FEEDBACK SYNTHESIS AND MINIMAL TIME FUNCTION FOR THE BIOREMEDIATION OF WATER RESOURCES WITH TWO PATCHES

H. RAMÍREZ†, A. RAPAPORT‡, AND V. RIQUELME§

Abstract. This paper studies the bioremediation, in minimal time, of a water resource or reservoir using a single continuous bioreactor. The bioreactor is connected to two pumps, at different locations in the reservoir, that pump polluted water and inject back sufficiently clean water with the same flow rate. This leads to a minimal-time optimal control problem where the control variables are related to the inflow rates of both pumps. We obtain a nonconvex problem for which it is not possible to directly prove the existence of its solutions. We overcome this difficulty and fully solve the studied problem by applying Pontryagin’s principle to the associated generalized control problem. We also obtain explicit bounds on its value function via Hamilton–Jacobi–Bellman techniques.

Key words. minimal-time control, nonconvexity, feedback synthesis, value function, Pontryagin’s maximum principle, Hamilton–Jacobi–Bellman equation, decontamination, water resources, chemostat

DOI. 10.1137/140989443

1. Introduction. Today, the decontamination of water resources and reservoirs in natural environments (lakes, lagoons, etc.) and in industrial frameworks (basins, pools, etc.) is of prime importance. Due to the availability of drinking water becoming scarce on earth, efforts have to be made to reuse water and to preserve aquatic resources. To this end, biological treatment is a convenient way to extract organic or soluble matter from water. The basic principle is to use biotic agents (generally microorganisms) that convert the pollutant until the concentration in the reservoir decreases to an acceptable level. Typically, the treatment is performed with the help of continuously stirred or fed-batch bioreactors. Numerous studies have been devoted to this subject over the past 40 years (see, for instance, [1, 2, 3, 13, 15, 17, 20, 21, 24, 25, 26]). The following main types of procedures are usually considered:

1. Continuous bioreactors, which are maintained at a constant operating and physiological state.
2. Fed-batch bioreactors, which are subjected to a periodic feeding.
3. Chemostat bioreactors, which are subjected to a periodic dilution.
The direct introduction of the biotic agents to the reservoir. This solution could lead to the eutrophication of the resource.

- The draining of the reservoir to a dedicated bioreactor and the filling back of the water after treatment. This solution attempts to eradicate various forms of life supported by the water resource, that cannot survive without water (such as fish, algae, etc.).

Alternatively, one can consider a side bioreactor that continuously treats the water pumped from the reservoir and that injects it back with the same flow rate so that the volume of the reservoir remains constant at all time. At the output of the bioreactor, a settler separates biomass from the water so that no biomass is introduced in the resource. Such an operating procedure is typically used for water purification of culture basins in aquaculture [8, 11, 18].

The choice of the flow rate presents a trade-off between the speed at which the water is treated and the quality of decontamination. Recently, minimal-time control problems with simple spatial representations have been formulated and addressed [5, 12]. Under the assumption that the resource is perfectly mixed, an optimal state feedback that depends on the characteristics of the microorganisms and on the online measurement of the pollutant concentration has been derived. Later, an extension with a more realistic spatial representation was proposed in [14] that considers two perfectly mixed zones in the resource: an “active” zone, where the treatment of the pollutant is the most effective, and a more confined or “dead” zone that communicates with the active zone by diffusion of the pollutant. It has been shown that the optimal feedback obtained for the perfectly mixed case is also optimal when one applies it on the pollutant concentration in the active zone only. The fact that this controller does not require knowledge of the size of the dead zone or of the value of the diffusion parameter, nor of the online measurement of the pollutant in the dead zone, is a remarkable property. Nevertheless, the minimal time is impacted by the characteristics of the confinement.

In the present work, we consider that the treatment of the water resource can be split into two zones, i.e., the water is extracted from the resource at two different points (instead of one), and the treated water returns to the resource (with the same flows) at two different locations. A diffusion makes connection between the zones (see Figure 1). Such a division into two patches can represent real situations such as
the following:

- natural environments where water tables or lagoons are connected together
  by a small communication path (this modeling covers also the particular case of
  a null diffusion when one has to treat two independent volumes);
- resource hydrodynamics that reveal influence zones for each pumping devices,
  depending on the locations of the extraction and return points;
- accidental pollution as a homogeneous strain diffusing into the complementary
  part of the resource.

The control problem consists in choosing dynamically the total flow rate \( q \) and the
flow distribution \( q_1, q_2 \) between the two patches, with the objective of having both
of them decontaminated in minimal time. Notice that a particular strategy consists
in having all the time a flow distribution entirely with one zone, which amounts to
the former problem with active and dead zones mentioned above. We study here
the benefit of switching dynamically the treatment to the other patch or treating
simultaneously both patches. The associated minimal-time problem is significantly
more complex, because there are two controls and the velocity set is nonconvex (this
is shown in the next section). Indeed, it is necessary to use different techniques to
address the cases of nonnull diffusion between the two zones and the limiting case of
null diffusion between the two zones.

The paper is organized as follows. In the next section, definitions and assump-
tions are presented. In section 3, properties of the optimization problem with relaxed
controls and nonnull diffusion are investigated. In section 4, the optimal control strat-
ogy for the original problem with nonnull diffusion is given and proven. In section 5,
we address the particular case of null diffusion and we provide explicit bounds on the
minimal-time function. Finally, we show numerical computations that illustrate the
theoretical results, and give concluding remarks.

2. Definitions and preliminaries. In what follows, we denote by \( \mathbb{R} \) the set of
real numbers, \( \mathbb{R}_+ \) and \( \mathbb{R}_+^* \) the sets of nonnegative and positive real numbers, respec-
tively. Analogously, \( \mathbb{R}_- \) and \( \mathbb{R}_-^* \) are the sets of nonpositive and negative real numbers,
respectively. We set also \( \mathbb{R}_2^* = \mathbb{R}_+ \times \mathbb{R}_+^* \) and \( \mathbb{R}_2 = \mathbb{R}_- \times \mathbb{R}_- \).

The time evolution of the concentrations \( s_i \) \( (i = 1, 2) \) of pollutants in the two
patches are given by the equations

\[
\begin{align*}
\frac{ds_1}{dt} &= \frac{q_1}{v_1}(s_r - s_1) + \frac{D}{v_1}(s_2 - s_1), \\
\frac{ds_2}{dt} &= \frac{q_2}{v_2}(s_r - s_2) + \frac{D}{v_2}(s_1 - s_2),
\end{align*}
\]

(2.1)

where the volumes \( v_i \) \( (i = 1, 2) \) are assumed to be constant and \( D \) denotes the diffusion
coefficient of the pollutant between the two zones. The control variables are the
flow rates \( q_i \) of the pumps in each zone, which bring water with a low pollutant
concentration \( s_r \) from the bioreactor and remove water with a pollutant concentration
\( s_i \) from each zone \( i \), with the same flow rates \( q_i \).

The concentration \( s_r \) at the output of the bioreactor is linked to the total flow
rate \( q = q_1 + q_2 \) by the usual chemostat model

\[
\begin{align*}
\frac{ds_r}{dt} &= -\mu(s_r)x_r + \frac{q}{v_r}(s_{in} - s_r), \\
\frac{dx_r}{dt} &= \mu(s_r)x_r - \frac{q}{v_r}x_r,
\end{align*}
\]

where $x_t$ is the biomass concentration, $v_t$ is the volume of the bioreactor, and $\mu(\cdot)$ is the specific growth rate of the bacteria (without loss of generality we assume that the yield coefficient is equal to one). These equations describe the dynamics of a bacterial growth consuming a substrate that is constantly fed in a tank of constant volume (see, for instance, [23]). The input concentration $s_{in}$ is given here by the combination of the concentrations of the water extracted from the two zones:

$$s_{in} = \frac{q_1 s_1 + q_2 s_2}{q_1 + q_2}. \tag{2.3}$$

We assume that the output of the bioreactor is filtered by a settler that we assume to be perfect, so that the water that returns to the resource is biomass free (see [9, 10] for considerations of settler modeling and conditions that ensure the stability of the desired steady state of the settler).

The target to be reached in the minimal time is defined by a threshold $\underline{s} > 0$ of the pollutant concentrations, that is

$$T = \{ s = (s_1, s_2) \in \mathbb{R}_+^2 \mid \max(s_1, s_2) \leq \underline{s} \}.$$  

In the paper, we shall denote $t_f$ as the first time at which a trajectory reaches the target (when it exists).

We consider the usual assumptions on the growth function $\mu(\cdot)$ in the absence of inhibition.

**Assumption 1.** $\mu(\cdot)$ is a $C^1$ increasing concave function defined on $\mathbb{R}_+$ with $\mu(0) = 0$.

Under this last assumption, we recall that under a constant $s_{in}$, the dynamics (2.2) admit a unique positive equilibrium $(s_t^*, x_t^*)$ that is globally asymptotically stable on the domain $\mathbb{R}_+ \times \mathbb{R}_+^*$ provided that the condition $q/v_t \leq \mu(s_{in})$ is satisfied (see, for instance, [23]). Then, $s_t^*$ is defined as the unique solution of $\mu(s_t^*) = q/v_t$ and $x_t^* = s_{in} - s_t^*$. Consequently, considering expression (2.3), the controls $q_1$ and $q_2$ are chosen such that

$$q_1 + q_2 \leq v_t \mu \left( \frac{q_1 s_1 + q_2 s_2}{q_1 + q_2} \right).$$

We assume that the resource to be treated is very large. This amounts to considering that the bioreactor is small compared to both zones of the resource.

**Assumption 2.** $v_1$ and $v_2$ are large compared to $v_t$.

Let us define $\alpha = q_1/q$, $r = v_1/(v_1 + v_2)$, $d = D/v_t$, and $\epsilon = v_t/(v_1 + v_2)$. Then, the coupled dynamics (2.1)–(2.2) with (2.3) can be written in the slow-fast form

$$\begin{align*}
\frac{ds_t}{dt} &= -\mu(s_t)x_t + \frac{q}{v_t}(\alpha s_1 + (1 - \alpha)s_2 - s_t), \\
\frac{dx_t}{dt} &= \mu(s_t)x_t - \frac{q}{v_t}x_t,
\end{align*}$$

$$\begin{align*}
\frac{ds_1}{dt} &= \epsilon \left( \frac{\alpha}{r} \frac{q}{v_t} (s_t - s_1) + \frac{d}{r} (s_2 - s_1) \right), \\
\frac{ds_2}{dt} &= \epsilon \left( \frac{1 - \alpha}{1 - r} \frac{q}{v_t} (s_t - s_2) + \frac{d}{1 - r} (s_1 - s_2) \right). \tag{2.4}
\end{align*}$$

Provided that the initial conditions of the variables $(s_t, x_t)$ belong to $\mathbb{R}_+ \times \mathbb{R}_+^*$, applying Tikonov’s theorem (see, for instance, [16]), the dynamics of the slow variables
(s_1, s_2) can be approached using the reduced dynamics

\[
\begin{align*}
\dot{s}_1 &= \frac{ds_1}{d\tau} = \frac{\alpha}{r} \mu(s_t^*)(s_t^* - s_1) + \frac{d}{r} (s_2 - s_1), \\
\dot{s}_2 &= \frac{ds_2}{d\tau} = 1 - \frac{\alpha}{1-r} \mu(s_t^*)(s_t^* - s_2) + \frac{d}{1-r} (s_1 - s_2)
\end{align*}
\]

in the time scale \( \tau = ct \). In this formulation, the quasi-steady-state concentration \( s_t^* \)
of the bioreactor can be considered as a control variable that takes values in \([0, \alpha s_1 + (1 - \alpha) s_2]\), which is equivalent to choosing \( q \in [0, v_s \mu(\alpha s_1 + (1 - \alpha) s_2)] \) when Assumption 1 is satisfied. In the following, we shall consider the optimal control for the reduced dynamics only. Nevertheless, we give some properties of the optimal feedback for the reduced dynamics when applied to the unreduced one, in section 4 (Remark 2) and the appendix.

Notice that the control problem can be reformulated with the controls \( u = (\alpha, s_t^*) \) that belong to the state-dependent control set

\[ U(s) = \{(\alpha, s_t^*) | \alpha \in [0,1], s_t^* \in [0, \alpha s_1 + (1 - \alpha) s_2]\} \]

equivalently to controls \( q_1 \) and \( q_2 \). In what follows, a measurable function \( u(\cdot) \) such that \( u(t) \in U(s(t)) \) for all \( t \) is called an admissible control.

**Lemma 2.1.** The domain \( \mathbb{R}_+^2 \) is positively invariant by the dynamics (2.5) for any admissible controls \( u(\cdot) \), and any trajectory is bounded. Furthermore, the target \( \mathcal{T} \) is reachable in a finite time from any initial condition in \( \mathbb{R}_+^2 \).

**Proof.** For \( s_1 = 0 \) and \( s_2 \geq 0 \), one has \( \dot{s}_1 \geq 0 \). Similarly, one has \( \dot{s}_2 \geq 0 \) when \( s_1 \geq 0 \) and \( s_2 = 0 \). By the uniqueness of the solutions of (2.5) for measurable controls \( u(\cdot) \), we deduce that \( \mathbb{R}_+^2 \) is invariant. From (2.5), one can write

\[ rs_1 + (1-r)\dot{s}_2 = \mu(s_t^*)(s_t^* - (\alpha s_1 + (1 - \alpha) s_2)) \leq 0 \]

for any admissible controls. One then deduces

\[ rs_1(t) + (1-r)s_2(t) \leq M_0 = rs_1(0) + (1-r)s_2(0) \quad \forall t \geq 0, \]

which provides the boundedness of the trajectories.

Consider the feedback strategy

\[ \alpha = r, \quad s_t^* = \frac{rs_1 + (1-r)s_2}{2}, \]

and we write the dynamics of \( m = rs_1 + (1-r)s_2 \) as follows:

\[ \dot{m} = -\mu \left( \frac{m}{2} \right) \frac{m}{2} < 0 \quad \forall m > 0. \]

Then, from any initial condition in \( \mathbb{R}_+^2 \), the solution \( m(t) \) tends to 0 when \( t \) tends to infinity. Therefore, \( m(\cdot) \) reaches the set \([0, \min(r, 1-r)s] \) in a finite time, which guarantees that \( s = (s_1, s_2) \) belongs to \( \mathcal{T} \) at that time.

For simplicity, we define the function

\[ \beta(\sigma, s_t^*) = \mu(s_t^*)(\sigma - s_t^*) \]
so that the dynamics (2.5) can be written in the more compact form

$$\dot{s} = F(s, u) + dG(s),$$

where $F(\cdot)$ and $G(\cdot)$ are defined as follows:

$$F(s, (\alpha, s^*_1)) = \begin{bmatrix} \alpha & \beta(s_1, s^*_1) \\ 1 - \alpha & \beta(s_2, s^*_2) \end{bmatrix}, \quad G(s) = \begin{bmatrix} s_2 - s_1 \\ r \frac{s_1 - s_2}{1 - r} \end{bmatrix}.$$ 

The dynamics can be equivalently expressed in terms of controls $v = (\alpha, \zeta)$ that belong to the state-independent set $V = [0, 1]^2$ with the dynamics

$$\dot{s} = F(s, (\alpha, \zeta(\alpha s_1 + (1 - \alpha)s_2))) + dG(s)$$

which satisfy the usual regularity conditions for applying Pontryagin’s maximum principle for deriving necessary optimality conditions. One can notice that the velocity set of the dynamics (2.7) is not everywhere convex. Consequently, one cannot guarantee a priori the existence of an optimal control $v(\cdot)$ in the set of time-measurable functions that take values in $V$ but that are among relaxed controls (see, for instance, [27, sect. 2.7]). For convenience, we shall keep the formulation of the problem with controls $u$. Because for any $s$ the sets $\cup_{u \in U(s)} F(s, u)$ are two-dimensional connected, the corresponding convexified dynamics can be written as follows (see [19, Thm. 2.29]):

$$\dot{s} = \tilde{F}(s, \tilde{u}) + dG(s)$$

with

$$\tilde{F}(s, \tilde{u}) = pF(s, u_a) + (1 - p)F(s, u_b)$$

where the relaxed controls $\tilde{u} = (u_a, u_b, p) = (\alpha_a, s^*_{ra}, \alpha_b, s^*_{rb}, p)$ belong to the set

$$\tilde{U}(s) = U(s)^2 \times [0, 1].$$

In the next section, we show that the relaxed problem admits an optimal solution that is also a solution of the original (nonrelaxed) problem.

**3. Study of the relaxed problem.** Throughout this section, we assume that the parameter $d$ is positive. The particular case of $d = 0$ will be considered later in section 5. Let us write the Hamiltonian of the relaxed problem

$$\tilde{H}(s, \lambda, (\alpha_a, s^*_{ra}, \alpha_b, s^*_{rb}, p)) = -1 + pQ(s, \lambda, (\alpha_a, s^*_{ra})) + (1 - p)Q(s, \lambda, (\alpha_b, s^*_{rb})) + d(s_2 - s_1) \left( \frac{\lambda_1}{r} - \frac{\lambda_2}{1 - r} \right)$$

which is to be maximized w.r.t. $(\alpha_a, s^*_{ra}, \alpha_b, s^*_{rb}, p) \in \tilde{U}(s)$, where $\lambda = (\lambda_1, \lambda_2)$, and we have defined, for convenience, the function

$$Q(s, \lambda, (\alpha, s^*)) = -\left( \frac{\alpha}{r} \beta(s_1, s^*_1) + (1 - \alpha) \frac{\lambda_2}{1 - r} \beta(s_2, s^*_2) \right).$$

The adjoint equations are

$$\begin{cases} \dot{\lambda}_1 = \lambda_1 \left( p \frac{\alpha_a}{r} \mu(s^*_{ra}) + (1 - p) \frac{\alpha_b}{r} \mu(s^*_{rb}) + \frac{d}{r} \right) - \lambda_2 \frac{d}{1 - r}, \\ \dot{\lambda}_2 = -\lambda_1 \frac{d}{r} + \lambda_2 \left( p \frac{1 - \alpha_a}{1 - r} \mu(s^*_{ra}) + (1 - p) \frac{1 - \alpha_b}{1 - r} \mu(s^*_{rb}) + \frac{d}{1 - r} \right) \end{cases}$$

Copyright © by SIAM. Unauthorized reproduction of this article is prohibited.
with the following transversality conditions

\[
\begin{align*}
  s_1(t_f) & < s, \quad s_2(t_f) = s \quad \Rightarrow \quad \lambda_1(t_f) = 0, \; \lambda_2(t_f) < 0, \\
  s_1(t_f) = s, \quad s_2(t_f) < s & \quad \Rightarrow \quad \lambda_1(t_f) < 0, \; \lambda_2(t_f) = 0, \\
  s_1(t_f) = s, \quad s_2(t_f) = s & \quad \Rightarrow \quad \lambda_1(t_f) \leq 0, \; \lambda_2(t_f) \leq 0 \text{ with } \lambda(t_f) \neq 0.
\end{align*}
\]

(3.4)

As usual, a triple \((s(\cdot), \lambda(\cdot), \dot{u}^*(\cdot))\) satisfying (2.8), (3.3), (3.4), and

\[
\dot{H}(s(t), \lambda(t), \dot{u}^*(t)) = \max_{\dot{u} \in \mathcal{U}(s(t))} \dot{H}(s(t), \lambda(t), \dot{u})
\]

is called an admissible extremal.

**Lemma 3.1.** Along any admissible extremal, one has \(\lambda_i(t) < 0 \) \((i = 1, 2)\) for any \(t < t_f\).

**Proof.** If one writes the adjoint equations (3.3) as \(\dot{\lambda}_i = \phi_i(t, \lambda_1, \lambda_2) \) \((i = 1, 2)\), one can notice that the partial derivatives \(\partial_j \phi_i \) \((i \neq j)\) are nonpositive. From the theory of monotone dynamical systems (see, for instance, [22]), the dynamics (3.3) is thus competitive or, equivalently, cooperative in backward time. As the transversality conditions (3.4) gives \(\lambda_i(t_f) \leq 0 \) \((i = 1, 2)\), we deduce by the property of monotone dynamics that one should have \(\lambda_i(t) \leq 0 \) \((i = 1, 2)\) for any \(t \leq t_f\). Moreover, \(\lambda = 0\) is an equilibrium of (3.3) and \(\lambda(t_f)\) has to be different from 0 at any time \(t \leq t_f\). Then, \(\lambda_i(t) \) \((i = 1, 2)\) cannot be simultaneously equal to zero. If there exists \(i < t_f\) and \(i \in \{1, 2\}\) such that \(\lambda_i(t) = 0\), then one should have \(\lambda_i(t) < 0\) for \(j \neq i\). However, \(d > 0\) implies \(\dot{\lambda}_i(t) > 0\), thus obtaining a contradiction with \(\lambda_i(t) < 0\) for any time. \(\square\)

For the following, we consider the function

\[
\gamma(\sigma) = \max_{s_i \geq 0} \beta(\sigma, s_i^*), \quad \sigma > 0,
\]

(3.5)

which satisfies the following property.

**Lemma 3.2.** Under Assumption 1, for any \(\sigma > 0\), there exists a unique \(s_i^*(\sigma) \in (0, \sigma)\) that realizes the maximum in (3.5). Furthermore, the function \(\gamma(\cdot)\) is differentiable and increasing with

\[
\gamma'(\sigma) = \mu(s_i^*(\sigma)).
\]

(3.6)

**Proof.** Consider the function \(\varphi : (\sigma, w) \in \mathbb{R}_+ \times [0, 1] \mapsto \beta(\sigma, w\sigma)\) and the partial function \(\varphi_\sigma : w \in [0, 1] \mapsto \varphi(\sigma, w)\) for fixed \(\sigma > 0\). Notice that \(\varphi_\sigma(0) = \varphi(1) = 0\) and that \(\varphi_\sigma(w) > 0\) for \(w \in (0, 1)\). Simple calculation gives \(\varphi''_\sigma(w) = \mu''(w\sigma)(1-w)\sigma^3 - 2\mu'(w\sigma)\sigma^2\), which is negative. Therefore, \(\varphi_\sigma(\cdot)\) is a strictly concave function on \([0, 1]\) and consequently admits a unique maximum \(w_\sigma^*\) on \([0, 1]\). We conclude that \(w_\sigma^*\) belongs to \((0, 1)\) or, equivalently, that the maximum of \(s_i^* \mapsto \beta(\sigma, s_i^*)\) is realized for a unique \(s_i^*(\sigma) = w_\sigma^*\sigma\) in \((0, \sigma)\).

Furthermore, one has \(\varphi''_\sigma(w) = \sigma\mu'(w\sigma)(\sigma - w\sigma) - \sigma\mu(w\sigma)\), and the necessary optimality condition \(\varphi''_\sigma(w_\sigma^*) = 0\) gives the equality

\[
\mu(s_i^*(\sigma)) = \mu'(s_i^*(\sigma))(\sigma - s_i^*(\sigma)).
\]

(3.7)

Simple calculation shows that for each \(w \in [0, 1]\), the function \(\sigma \mapsto \varphi(\sigma, w)\) is convex. Because the maximizer \(w_\sigma^*\) of \(\varphi_\sigma(\cdot)\) is unique for any \(\sigma\), one can apply the rules of
differentiability of pointwise maxima (see, for instance, [7, Chap. 2.8]), which state that the function \( \gamma(\sigma) = \max_{w \in [0,1]} \varphi(\sigma, w) \) is differentiable with

\[
\gamma'(\sigma) = \frac{\partial \varphi}{\partial \sigma}(\sigma, w^*_\sigma) = w^*_\sigma \mu'(w^*_\sigma \sigma) + \mu(w^*_\sigma \sigma)(1 - w^*_\sigma).
\]

Equation (3.7) provides the simpler expression (3.6), which shows that \( \gamma(\cdot) \) is increasing.

We now consider the variable

\[
\eta = \frac{-\lambda_1}{r} \gamma(s_1) - \frac{-\lambda_2}{1-r} \gamma(s_2)
\]

which will play the role of a switching function. Notice that this is not the usual switching function of problems with linear dynamics w.r.t. a scalar control because our problem has two controls \( \alpha \) and \( s^*_\sigma \) that cannot be separated, and the second control acts nonlinearly in the dynamics.

**Lemma 3.3.** For fixed \((s, \lambda) \in \mathbb{R}^2 \times \mathbb{R}^2\), the pairs \( u^* = (\alpha, s^*_\sigma) \in U(s) \) that maximize the function \( Q(s, \lambda, \cdot) \) are the following:

i. when \( \eta > 0 \): \( u^* = (1, \hat{s}^*_\sigma(s_1)) \);

ii. when \( \eta < 0 \): \( u^* = (0, \hat{s}^*_\sigma(s_2)) \);

iii. when \( \eta = 0 \) and \( s_1 = s_2 \): \( u^* \in [0,1] \times \{ \hat{s}^*_\sigma \} \), where \( \hat{s}^*_\sigma = \hat{s}^*_\sigma(s_1) = \hat{s}^*_\sigma(s_2) \);

iv. when \( \eta = 0 \) and \( s_1 \neq s_2 \): \( u^* = (1, \hat{s}^*_\sigma(s_1)) \) or \( u^* = (0, \hat{s}^*_\sigma(s_2)) \).

**Proof.** When \( \eta > 0 \), one can write, using Lemma 3.2 and \( \lambda_1, \lambda_2 < 0 \),

\[
Q(s, \lambda, (1, \hat{s}^*_\sigma(s_1))) = \frac{-\lambda_1}{r} \gamma(s_1) > \frac{-\lambda_1}{r} \gamma(s_1) + (1 - \alpha) \frac{-\lambda_2}{1-r} \gamma(s_2) \quad \forall \alpha \in [0,1)
\]

\[
\geq \frac{-\lambda_1}{r} \beta(s_1, s^*_\sigma) + (1 - \alpha) \frac{-\lambda_2}{1-r} \beta(s_2, s^*_\sigma) \quad \forall \alpha \in [0,1)
\]

\[
\forall s^*_\sigma \in [0, \alpha s_1 + (1 - \alpha) s_2]
\]

\[
Q(s, \lambda, (\alpha, s^*_\sigma)) \quad \forall \alpha \in [0,1) \forall s^*_\sigma \in [0, \alpha s_1 + (1 - \alpha) s_2],
\]

and for \( \alpha = 1 \), one has \( Q(s, \lambda, (1, \hat{s}^*_\sigma(s_1))) > Q(s, \lambda, (1, s^*_\sigma)) \forall s^*_\sigma \neq \hat{s}^*_\sigma(s_1) \). Therefore, the maximum of \( Q(s, \lambda, \cdot) \) is reached for the unique pair \((\alpha, s^*_\sigma) = (1, \hat{s}^*_\sigma(s_1))\).

Similarly, when \( \eta < 0 \), one can show that the unique maximum is \((\alpha, s^*_\sigma) = (0, \hat{s}^*_\sigma(s_2))\).

When \( \eta = 0 \), one has

\[
\frac{-\lambda_1}{r} \gamma(s_1) = \frac{-\lambda_2}{1-r} \gamma(s_2) > Q(s, \lambda, (\alpha, s^*_\sigma)) \quad \forall \alpha \in [0,1) \forall s^*_\sigma \notin \{ \hat{s}^*_\sigma(s_1), \hat{s}^*_\sigma(s_2) \}.
\]

If \( s_1 = s_2 \), one necessarily has \( \lambda_1/r = \lambda_2/(1-r) \neq 0 \), and thus

\[
Q(s, \lambda, (\alpha, s^*_\sigma)) = \frac{-\lambda_1}{r} \beta(s_1, s^*_\sigma) < \frac{-\lambda_1}{r} \gamma(s_1) = Q(s, \lambda, (\alpha, \hat{s}^*_\sigma(s_1))) \forall s^*_\sigma \neq \hat{s}^*_\sigma(s_1)
\]

for any \( \alpha \in [0,1] \). The optimal \( s^*_\sigma \) is necessarily equal to \( \hat{s}^*_\sigma(s_1) = \hat{s}^*_\sigma(s_2) \).

If \( s_1 \neq s_2 \), one has \( \hat{s}^*_\sigma(s_1) \neq \hat{s}^*_\sigma(s_2) \) and, consequently, using Lemma 3.2 and the fact that \( \lambda_1 \) and \( \lambda_2 \) are both negative,

\[
Q(s, \lambda, (\alpha, \hat{s}^*_\sigma(s_1))) = \alpha \frac{-\lambda_1}{r} \gamma(s_1) + (1 - \alpha) \frac{-\lambda_2}{1-r} \beta(s_2, \hat{s}^*_\sigma(s_1)) < \frac{-\lambda_1}{r} \gamma(s_1) \forall \alpha \in [0,1),
\]
Then, \((\alpha, s^*_1) = (1, \hat{s}^*_1(s_1))\) and \((\alpha, s^*_2) = (0, \hat{s}^*_2(s_2))\) are the only two pairs that maximize \(Q(s, \lambda, \cdot)\).

**Proposition 3.4.** At almost any time, an optimal control \(\hat{u}^*\) of the relaxed problem satisfies the following property:

1. when \(\eta \neq 0\) or \(s_1 = s_2\), one has \(\hat{F}(s, \hat{u}^*) = F(s, u^*)\), where \(u^*\) is given by Lemma 3.3i–iii.

2. when \(\eta = 0\) and \(s_1 \neq s_2\), one has

\[
\hat{u}^* \in \{(1, \hat{s}^*_1(s_1)), (0, \hat{s}^*_2(s_2))\} \times U(s) \times \{1\}
\cup U(s) \times \{(1, \hat{s}^*_1(s_1)), (0, \hat{s}^*_2(s_2))\} \times \{0\}
\cup \{(1, \hat{s}^*_1(s_1), 0, \hat{s}^*_2(s_2))\} \times [0, 1]
\cup \{(0, \hat{s}^*_2(s_2), 1, \hat{s}^*_1(s_1))\} \times [0, 1].
\]

**Proof.** According to Pontryagin’s maximum principle, an optimal control \(\hat{u} = (u_a, u_b, p)\) has to maximize at almost any time \(t\) the Hamiltonian \(\hat{H}\) given in (3.1) or, equivalently, the quantity

\[
(u_a, u_b, p) \mapsto \hat{Q}(s, \lambda, \cdot) = pQ(s, \lambda, u_a) + (1 - p)Q(s, \lambda, u_b),
\]

where \(\lambda_1\) and \(\lambda_2\) are negative (from Lemma 3.1). Let us consider the maximization of the function \(Q(s, \lambda, \cdot)\) characterized by Lemma 3.3.

In cases i and ii, the function \(Q(s, \lambda, \cdot)\) admits a unique maximizer \(u^*\). Thus, \(\hat{Q}(s, \lambda, \cdot)\) is maximized for \(u_a = u^*\) with \(p = 1\) independent of \(u_b\) (or, symmetrically, for \(u_b = u^*\) with \(p = 0\) independent of \(u_a\)) or for \(u_a = u_b = u^*\) independent of \(p \in [0, 1]\). In any case, one has \(\hat{F}(s, \hat{u}^*) = F(s, u^*)\).

In case iii, the function \(Q(s, \lambda, \cdot)\) is maximized for a unique value of \(s^*_1 = \hat{s}^*_1(s_1) = \hat{s}^*_2(s_2)\) independent of \(\alpha\). Thus, \(\hat{Q}(s, \lambda, \cdot)\) is maximized when \(s^*_1\) is equal to this value with \(p = 1\) independent of \(u_b\) (and, symmetrically, when \(s^*_b\) is equal to this value with \(p = 0\) independent of \(u_a\)) or when both \(s^*_a\) and \(s^*_b\) are equal to this value independent of \(\alpha_a, \alpha_b, \) and \(p\). In any case, one has \(\hat{F}(s, \hat{u}^*) = F(s, u^*)\), where \(u^* \in [0, 1] \times \{s^*_1\}\).

In case iv, the function \(Q(s, \lambda, \cdot)\) admits two possible maximizers. Thus, \(\hat{Q}(s, \lambda, \cdot)\) is maximized when \(u_a\) is equal to one of these maximizers with \(p = 1\) independent of \(u_b\), when, symmetrically, \(u_b\) is equal to one of these maximizers with \(p = 0\) independent of \(u_a\), or when \(u_a\) and \(u_b\) are equal to the two different maximizers independent of \(p\). All these cases appear in the set membership (3.8).

**Remark 1.** In case 2 of Proposition 3.4, a relaxed control \(\hat{u}^*\) with \(p \in [0, 1]\) can be approximated by a high-frequency switching between nonrelaxed controls \(u = (1, \hat{s}^*_1(s_1))\) and \(u = (0, \hat{s}^*_2(s_2))\) (see the “chattering control” in [5]). In practice, such a high-frequency switching between the two pumps is not desired.

The following lemma will be crucial later at several places.

**Lemma 3.5.** Along any extremal trajectory, one has at almost any time

\[
\dot{\eta} = d \left( \frac{\gamma(s_1) + \gamma(s_2)}{r} \right) \left( \frac{\lambda_2}{1 - r} - \frac{\lambda_1}{r} \right)
+ d \left( \frac{\lambda_1}{r^2} \mu(\hat{s}^*_1(s_1)) + \frac{\lambda_2}{(1 - r)^2} \mu(\hat{s}^*_2(s_2)) \right) (s_1 - s_2).
\]
Furthermore, the optimal control dynamics (2.8) are admissible optimal trajectories for the original dynamics (2.6). Furthermore, the optimal control $u^*(\cdot)$ satisfies the following property

$$s_1(t) \neq s_2(t) \implies u^*(t) = \{1, \hat{s}_1^*(s_1)\} \text{ or } u^*(t) = \{0, \hat{s}_2^*(s_2)\} \quad \text{for a.e. } t \in [0, t_f].$$

**Proof.** Let us write the time derivatives of the products $\lambda_1 \gamma(s_1)$ and $\lambda_2 \gamma(s_2)$ that appear in the expression of the function $\eta$ using expressions (2.8), (3.3), and (3.6):

$$\frac{d}{dt} [\lambda_1 \gamma(s_1)] = \frac{\lambda_1}{r} \delta_1 + d\gamma(s_1) \left( \frac{\lambda_1}{r} - \frac{\lambda_2}{1 - r} \right) + \frac{\lambda_1}{r} \mu(\hat{s}_1^*(s_1))(s_2 - s_1),$$

where we put

$$\delta_1 = p \alpha_\alpha [\mu(s_\alpha^*) \gamma(s_1) - \mu(\hat{s}_1^*(s_1))\beta(s_1, s_\alpha^*)] + (1 - p) \alpha_b [\mu(s_b^*) \gamma(s_1) - \mu(\hat{s}_1^*(s_1))\beta(s_1, s_b^*)].$$

One can easily check that for any optimal control $\hat{u}^*$ given by Proposition 3.4, one has $\delta_1 = 0$. Similarly, one can write

$$\frac{d}{dt} [\lambda_2 \gamma(s_2)] = \frac{\lambda_2}{1 - r} \delta_2 + d\gamma(s_2) \left( \frac{\lambda_2}{1 - r} - \frac{\lambda_1}{r} \right) + \frac{\lambda_2}{1 - r} \mu(\hat{s}_2^*(s_2))(s_1 - s_2),$$

where

$$\delta_2 = p(1 - \alpha_\alpha) [\mu(s_\alpha^*) \gamma(s_2) - \mu(\hat{s}_2^*(s_2))\beta(s_2, s_\alpha^*)] + (1 - p)(1 - \alpha_b) [\mu(s_b^*) \gamma(s_2) - \mu(\hat{s}_2^*(s_2))\beta(s_2, s_b^*)],$$

with $\delta_2 = 0$ for any optimal control $\hat{u}^*$ given by Proposition 3.4.

Then, one obtains the equality (3.9). \hfill \square

We now prove that the nonrelaxed problem admits an optimal solution that is also optimal for the relaxed problem.

**Proposition 3.6.** The optimal trajectories for the problem with the convexified dynamics (2.8) are admissible optimal trajectories for the original dynamics (2.6). Furthermore, the optimal control $u^*(\cdot)$ satisfies the following property

$$s_1(t) \neq s_2(t) \implies u^*(t) = \{1, \hat{s}_1^*(s_1)\} \text{ or } u^*(t) = \{0, \hat{s}_2^*(s_2)\} \quad \text{for a.e. } t \in [0, t_f].$$

**Proof.** We will prove that the set of times whereby the optimal relaxed strategy generates a velocity that belongs to the convexified velocity set but not to the original velocity set has Lebesgue measure zero. For this, consider $s_1 > s_2$ and $\eta = 0$. Because $\gamma(\cdot)$ is increasing (see Lemma 3.2), $\gamma(s_1) > \gamma(s_2)$. Additionally, $\eta = 0$ implies that $\lambda_1/r > \lambda_2/(1 - r)$. From (3.9) of Lemma 3.5, we deduce the inequality $\hat{\eta} < 0$ (where $\lambda_1$ and $\lambda_2$ are negative by Lemma 3.1). Similarly, to consider $s_2 > s_1$ and $\eta = 0$ implies that $\hat{\eta} > 0$. We conclude that case 2 of Proposition 3.4 can only occur at times in a set of null measure, from which the statement follows.

Now, because the optimal strategy of the convexified problem is (at almost any time) an admissible extremal for the original problem, and because the optimal time of the convexified problem is less than or equal to the optimal time of the original problem, the original problem has a solution, and it is characterized by point 1 of Proposition 3.4.

The last statement of the proposition follows from point 1 of Proposition 3.4. \hfill \square

4. **Synthesis of the optimal strategy.** According to Proposition 3.6, we can now consider optimal trajectories of the original (nonrelaxed) problem, knowing that the optimal strategy is “bang-bang” except on a possible singular arc that belongs to the diagonal set $\Delta := \{s \in \mathbb{R}_+^2 \text{ s.t. } s_1 = s_2\}$.

Proposition 4.1. For $d > 0$, the following feedback control drives any initial state in $\mathbb{R}_+^2 \setminus \mathcal{T}$ to the target $\mathcal{T}$ in minimal time:

$$
\begin{align*}
    u^*[s] &= \begin{cases} 
        (1, \hat{s}_1^*(s_1)) & \text{when } s_1 > s_2, \\
        (r, \hat{s}_1^*(s_1)) = (r, \hat{s}_2^*(s_2)) & \text{when } s_1 = s_2, \\
        (0, \hat{s}_2^*(s_2)) & \text{when } s_1 < s_2.
    \end{cases}
\end{align*}
$$

Proof. From Pontryagin’s maximum principle, a necessary optimality condition for an admissible trajectory is the existence of a solution to the adjoint system

$$
\begin{align*}
    \dot{\lambda}_1 &= \lambda_1 \frac{\alpha}{r} \mu(s_1^*) + d \left( \frac{\lambda_1}{r} - \frac{\lambda_2}{1 - r} \right), \\
    \dot{\lambda}_2 &= \lambda_2 \frac{1 - \alpha}{r} \mu(s_1^*) + d \left( \frac{\lambda_2}{1 - r} - \frac{\lambda_1}{r} \right),
\end{align*}
$$

with the transversality conditions (3.4) and where $u^* = (\alpha, s_1^*)$ maximizes the Hamiltonian

$$
    H(s, \lambda, u) = -1 + Q(s, \lambda, u) + d(s_2 - s_1) \left( \frac{\lambda_1}{r} - \frac{\lambda_2}{1 - r} \right)
$$

w.r.t. $u$.

Consider the set

$$
    I_- = \{(s, \eta) \in (\mathbb{R}_+^2 \setminus \mathcal{T}) \times \mathbb{R} \text{ s.t. } s_1 > s_2 \text{ and } \eta < 0\}.
$$

From expression (3.9), one obtains the property

$$
    s_1 > s_2 \text{ and } \eta < 0 \Rightarrow \dot{\eta} < 0
$$

using the facts that $\lambda_i$ ($i = 1, 2$) are negative (Lemma 3.1) and that $\gamma(\cdot)$ is increasing (Lemma 3.2). When $\eta < 0$, one has $u^* = (0, \hat{s}_1^*(s_2))$ from Lemma 3.3, and it is possible to write

$$
    \dot{s}_1 - \dot{s}_2 = -\frac{d}{r(1 - r)} (s_1 - s_2) + \frac{\gamma(s_2)}{1 - r},
$$

which shows that $s_1 - s_2$ remains positive for any future time. Thus, the set $I_-$ is positively invariant by the dynamics defined by systems (2.5) and (4.2). We deduce that the existence of a time $t < t_f$ such that $(s(t), \eta(t)) \in I_-$ implies $(s(t_f), \eta(t_f)) \in I_-$, and from the transversality condition (3.4), one obtains $\lambda_1(t_f) < \lambda_2(t_f) = 0$. Then, one should have $\eta(t_f) = -\lambda_1(t_f)\gamma(s_1(t_f))/r > 0$, thus obtaining a contradiction. Similarly, one can show that the set

$$
    I_+ = \{(s, \eta) \in (\mathbb{R}_+^2 \setminus \mathcal{T}) \times \mathbb{R} \text{ s.t. } s_1 < s_2 \text{ and } \eta > 0\}
$$

is positively invariant and that the transversality condition implies that $(s, \eta)$ never belongs to $I_+$ along an optimal trajectory. Because $\Delta$ is the only possible locus of a singular arc, we can form a conclusion about the optimality of (4.1) outside $\Delta$.

Now, consider the function

$$
    L(s) = \frac{1}{2} (s_1 - s_2)^2
$$

and write its time derivative along an admissible trajectory $s(\cdot)$ as follows:

$$
    \dot{L} = \langle \nabla L, \dot{s} \rangle = \left( -\frac{\alpha}{r} \beta(s_1, s_1^*) + \frac{1 - \alpha}{1 - r} \beta(s_2, s_2^*) \right) (s_1 - s_2) - \frac{2d}{r(1 - r)} L.
$$

Copyright © by SIAM. Unauthorized reproduction of this article is prohibited.
Along an optimal trajectory, one has

\[
\dot{L} + \frac{2d}{r(1-r)}L = \begin{cases} 
\frac{\gamma(s_1)}{r}(s_1 - s_2) & \text{when } s_1 > s_2, \\
\frac{\gamma(s_2)}{1-r}(s_1 - s_2) & \text{when } s_1 < s_2,
\end{cases}
\]

and deduces that the inequality \(\dot{L} + \frac{2d}{r(1-r)}L \leq 0\) is satisfied. Consequently, the set \(\Delta \subset L^{-1}(0)\) is positively invariant by the optimal dynamics. On \(\Delta\), the maximization of \(Q(s, \lambda, \cdot\)) gives the unique \(s_1^* = \hat{s}_1^*(s_1) = \hat{s}_1^*(s_2)\) because \(\lambda_1, \lambda_2\) are both negative (see Lemmas 3.1, 3.2, and 3.3). Finally, the only (nonrelaxed) control that leaves \(\Delta\) invariant is such that \(\alpha = r\).

**Remark 2.** The feedback (4.1) has been proved to be optimal for the reduced dynamics (2.5). In the appendix, we prove that this feedback drives the state of the unreduced dynamics (2.4) to the target in finite time, whatever is \(\epsilon > 0\).

**5. Study of the minimal-time function.** Define the function

\[
T(\sigma) = \max(0, \overline{T}(\sigma)) \quad \text{with} \quad \overline{T}(\sigma) = \int_\sigma^\infty \frac{d\xi}{\gamma(\xi)} , \quad \sigma > 0.
\]

**Lemma 5.1.** \(T(\cdot)\) is strictly concave on \([\underline{s}, +\infty)\).

**Proof.** Lemma 3.2 allows one to claim that \(\overline{T}(\cdot)\) is twice differentiable for any \(\sigma > 0\) and that one has

\[
\overline{T}''(\sigma) = -\frac{\gamma'(\sigma)}{\gamma(\sigma)^2} < 0 \quad \forall \sigma > 0.
\]

The function \(\overline{T}(\cdot)\) is strictly concave on \(\mathbb{R}_+\), and because \(T(\cdot)\) coincides with \(\overline{T}(\cdot)\) on \([\underline{s}, +\infty)\), we conclude that \(T(\cdot)\) is strictly concave on this interval.

Let us denote the minimal-time function by \(V_d(\cdot)\), indexed by the value of the parameter \(d\):

\[
V_d(x) = \inf_{u(\cdot)} \{ t > 0 \mid s(x, u, d, t) \in \mathcal{T} \},
\]

where \(s(x, u, d, \cdot)\) denotes the solution of (2.6) with the initial condition \(s(0) = x = (x_1, x_2)\), the admissible control \(u(\cdot)\), and the parameter value \(d\). Lemma 2.1 ensures that these functions are well defined on \(\mathbb{R}_+^2\).

**Proposition 5.2.** The value functions \(V_d(\cdot)\) satisfy the following properties:

i. For any \(d \geq 0\), \(V_d(\cdot)\) is Lipschitz continuous on \(\mathbb{R}_+^2\).

ii. For \(d = 0\), one has \(V_0(x) = rT(x_1) + (1-r)T(x_2)\) for any \(x \in \mathbb{R}_+^2\), and the feedback (4.1) is optimal for both relaxed and nonrelaxed problems.

**Proof.** On the boundary \(\partial^+ \mathcal{T}\) of the target that lies in the interior of the (positively) invariant domain \(\mathbb{R}_+^2\), the set \(N(\cdot)\) of unitary external normals is

\[
N(s) = \begin{cases} 
\begin{pmatrix} 0 \\ 1 \end{pmatrix} & \text{when } s_1 < \underline{s} \text{ and } s_2 = \underline{s}, \\
\begin{pmatrix} \cos \theta \\ \sin \theta \end{pmatrix} & \text{when } s_1 = s_2 = \underline{s}, \\
\begin{pmatrix} 1 \\ 0 \end{pmatrix} & \text{when } s_1 = \underline{s} \text{ and } s_2 < \underline{s}.
\end{cases}
\]

Copyright © by SIAM. Unauthorized reproduction of this article is prohibited.
At any \( s \in \partial^+ \mathcal{T} \), one has
\[
\inf_{u \in U(s)} \inf_{\nu \in N(s)} \langle F(s, u) + dG(s), \nu \rangle \leq \inf_{u \in U(s)} \inf_{\nu \in N(s)} \langle F(s, u), \nu \rangle = -\gamma(s) < 0 .
\]
Furthermore, the maps
\[
s \mapsto F(s, u) + dG(s)
\]
are Lipschitz continuous w.r.t. \( s \in \mathbb{R}_+^2 \) uniformly in \( u \). According to [4, sects. 1 and 4, Chap. IV], the target satisfies then the small time locally controllable property, and the value functions \( V_d(\cdot) \) are Lipschitz continuous on \( \mathbb{R}_+^2 \).

When \( d = 0 \), the feedback (4.1) provides the following dynamics:
\[
\dot{s} = \begin{cases} 
- \frac{1}{r} \begin{bmatrix} \gamma(s_1) \\ 0 \end{bmatrix} & \text{when } s_1 > \max(s_2, \underline{s}), \\
- \begin{bmatrix} \gamma(s_1) \\ \gamma(s_2) \end{bmatrix} & \text{when } s_1 = s_2 > \underline{s}, \\
- \frac{1}{r} \begin{bmatrix} 0 \\ \gamma(s_2) \end{bmatrix} & \text{when } s_2 > \max(s_1, \underline{s}), 
\end{cases}
\]
and one can explicitly calculate the time to go to the target for any initial condition \( x \in \mathbb{R}_+^2 \), which we denote as \( W_0(x) \):
\[
W_0(x) = \begin{cases} 
- r \int_{x_1}^{\max(x_2, \underline{x})} \frac{ds_1}{\gamma(s_1)} - \int_{\max(x_2, \underline{x})}^{x_2} \frac{ds_1}{\gamma(s_1)} & \text{when } x_1 \geq x_2, \\
- (1 - r) \int_{x_2}^{\max(x_1, \underline{x})} \frac{ds_2}{\gamma(s_2)} - \int_{\max(x_1, \underline{x})}^{x_1} \frac{ds_2}{\gamma(s_2)} & \text{when } x_1 \leq x_2.
\end{cases}
\]
One can check that \( W_0 \) is Lipschitz continuous and that it can be written as \( W_0(x) = rT(x_1) + (1 - r)T(x_2) \). We now show that \( W_0 \) is a viscosity solution of the Hamilton–Jacobi–Bellman equation associated with the relaxed problem
\[
(5.1) \quad \mathcal{H}(x, \nabla W_0(x)) = 0, \quad x \notin \mathcal{T},
\]
with
\[
\mathcal{H}(x, \nabla W_0(x)) = -1 + \max_{(u_a, u_b, p) \in \mathcal{U}(x)} pQ(x, -\nabla W_0(x), u_a) + (1 - p)Q(x, -\nabla W_0(x), u_b)
\]
(where \( Q \) is defined in (3.2)) and the boundary condition
\[
(5.2) \quad W_0(x) = 0, \quad x \in \mathcal{T}.
\]
Consider the \( C^1 \) functions
\[
\mathcal{W}_{0,1}(x) = rT(x_1), \quad \mathcal{W}_{0,2}(x) = (1 - r)T(x_2), \quad \text{and} \quad \mathcal{W}_0(x) = \mathcal{W}_{0,1}(x) + \mathcal{W}_{0,2}(x)
\]
defined on \( \mathbb{R}_+^2 \). One has
\[
\nabla \mathcal{W}_{0,1}(x) = \begin{bmatrix} r \\ \gamma(x_1) \\ 0 \end{bmatrix} \quad \text{and} \quad \nabla \mathcal{W}_{0,2}(x) = \begin{bmatrix} 0 \\ 1 - r \\ \gamma(x_2) \end{bmatrix}
\]
and obtain
\
\H(x, \nabla \nabla^{\hat{W}}_{0,1}(x)) = \H(x, \nabla \nabla^{\hat{W}}_{0,2}(x)) = \H(x, \nabla \nabla^{\hat{W}}_{0}(x)) = 0, \quad x \in \mathbb{R}^2_+,
\]
which shows that \(\hat{W}_{0,1}, \hat{W}_{0,2},\) and \(\hat{W}_{0}\) are solutions of (5.1) in the classical sense.

At \(x \notin \mathcal{T}\) with \(x_i \neq \underline{s}\) \((i = 1, 2),\) \(W_0\) is \(C^1\) and locally coincides with \(\hat{W}_0.\) Then, it satisfies (5.1) in the classical sense.

At \(x \notin \mathcal{T}\) with \(x_1 = s\) or \(x_2 = s,\) \(W_0\) is not differentiable but locally coincides with \(\max(\hat{W}_{0,1}, \hat{W}_{0,2})\) or \(\max(\hat{W}_{0,1}, \hat{W}_{0})\). From the properties of viscosity solutions (see, for instance, [4, Prop 2.1, Chap. II]), one must simply check that \(W_0\) is a supersolution of (5.1). At such points, the Fréchet subdifferential of \(W_0\) is
\[
\partial^- W_0(x) = \begin{cases} 
0, \frac{r}{\gamma(s)} \times \left\{ 1 - \frac{r}{\gamma(x_2)} \right\} & \text{when } x_1 = \underline{s}, \\
\frac{r}{\gamma(x_1)} \times \left\{ 0, \frac{1 - r}{\gamma(s)} \right\} & \text{when } x_2 = \underline{s}.
\end{cases}
\]
Because any subgradient \(\delta^- \in \partial^- W_0(x)\) is a nonnegative vector, one can again use Lemma 3.3 and obtain
\[
\H(x, \delta^-) = 0 \quad \forall \delta^- \in \partial^- W_0(x),
\]
which proves that \(W_0\) is a viscosity solution of (5.1). Moreover, \(W_0\) satisfies the boundary condition (5.2). Finally, we use the characterization of the minimal-time function as the unique viscosity solution of (5.1) in the class of Lipschitz continuous functions with boundary conditions (5.2) (see [4, Thm. 2.6, Chap IV]) to conclude that \(W_0\) is the value function of the relaxed problem. Because the time \(W_0(x)\) to reach the target from an initial condition \(x \notin \mathcal{T}\) is obtained with the nonrelaxed control (4.1), we also deduce that \(V_0\) and \(W_0\) are equal.

Remark 3. In the case \(d = 0,\) the control given by (4.1) is optimal but not the unique solution of the problem. Indeed, in Proposition 5.2, we proved that \(V_0:\) is the unique viscosity solution to (5.1), where one of the possible maximizers of the Hamiltonian given in (5.1) is given by (4.1), but on the set \((s, \infty)^2 \setminus \Delta\) there are more choices for \(u;\) for instance,
\[
u^*[s] = \begin{cases} 
(1, 2^*(s_1)) & \text{when } s_2 \leq \underline{s} < s_1, \\
(0, 2^*(s_2)) & \text{when } s_1 > s_2 > \underline{s}, \\
(r, 2^*(s_1)) = (r, 2^*(s_2)) & \text{when } s_1 = s_2, \\
(1, 2^*(s_1)) & \text{when } \underline{s} < s_1 < s_2, \\
(0, 2^*(s_2)) & \text{when } s_1 \leq \underline{s} < s_2
\end{cases}
\]
satisfies (5.1).

Proposition 5.3. The functions \(V_d:\) satisfy the following properties:

i. \(V_d(x) = T(x_1) + T(x_2)\) for any \(x \in \Delta\) and \(d \geq 0;\)

ii. \(V_\infty(x) = \lim_{d \to +\infty} V_d(x) = T(r x_1 + (1 - r) x_2)\) for any \(x \in \mathbb{R}^2_+;\) and

iii. \(d \mapsto V_d(x)\) is increasing for any \(x \in (s, \infty)^2 \setminus \Delta.\)

Proof. Consider an initial condition \(x \in \Delta \setminus \mathcal{T}.\) The optimal synthesis given in Proposition 4.1 shows that the set \(\Delta\) is invariant by the optimal flow and that the dynamics on \(\Delta\) are
\[
\dot{s}_i = -\gamma(s_i), \quad i = 1, 2,
\]
independent of \(d.\) We then conclude that \(V_d(x) = T(x_i)\) for \(i = 1, 2.\)
Consider $d > 0$ and $x \notin \Delta \cup \mathcal{T}$. Denote for simplicity $s(\cdot)$ as the solution $s(x, u^*, d, \cdot)$ with the feedback control $u^*$ given in Proposition 4.1, and $t_f = V_d(x)$. Define $t_\Delta$ as the first time $t$ such that $s(t) \in \Delta$ (here, we allow the solution $s(\cdot)$ to possibly enter the target $\mathcal{T}$ before reaching $\Delta$).

From (2.6) with control (4.1), one can easily check that the following inequalities are satisfied:

$$x_1 > x_2 \Rightarrow x_1 > s_1(t) \geq s_2(t) > x_2 \quad \forall t \in [0, t_\Delta] ,$$

$$x_1 < x_2 \Rightarrow x_1 < s_1(t) \leq s_2(t) < x_2 \quad \forall t \in [0, t_\Delta] .$$

Then, because the function $\gamma(\cdot)$ is increasing (Lemma 3.2), one can write, if the state $s$ has not yet reached $\Delta$,

$$|s_1 - s_2| - M_\Delta \leq \frac{d}{r(1-r)} |s_1 - s_2| - M_\Delta$$

with $M_\Delta = \min(\gamma(x_2)/r, \gamma(x_1)/(1-r))$ and $M_\Delta = \max(\gamma(x_1)/r, \gamma(x_2)/(1-r))$. Then, we obtain an upper bound on the time $t_\Delta$

$$t_\Delta \leq \frac{r(1-r)}{d} \log \left( 1 + \frac{d}{M_\Delta r(1-r)} |x_1 - x_2| \right)$$

which tends to zero when $d$ tends to infinity. From (5.3), we can also write

$$|x_1 - x_2| - M_\Delta t_\Delta \leq \frac{d}{r(1-r)} \int_0^{t_\Delta} |s_2(\tau) - s_1(\tau)| d\tau \leq |x_1 - x_2| - M_\Delta t_\Delta$$

and finally, one obtains from (2.6) the following bounds on $s_i(t_\Delta)$ ($i = 1, 2$):

$$r x_1 + (1-r) x_2 - \max(r, (1-r)) M_\Delta t_\Delta \leq s_i(t_\Delta) \leq r x_1 + (1-r) x_2 - \min(r, (1-r)) M_\Delta t_\Delta .$$

Therefore, $s_1(t_\Delta) = s_2(t_\Delta)$ converges to $r x_1 + (1-r) x_2$ when $d$ tends to $+\infty$. Furthermore, one has

$$t_f = t_\Delta + T(s(t_\Delta)) \quad \text{when} \; s(t_\Delta) \notin \mathcal{T} ,$$

$$t_f < t_\Delta \quad \text{when} \; s(t_\Delta) \in \mathcal{T} .$$

Because $t_\Delta \to 0$ and because $T(\cdot)$ is continuous with $T(r x_1 + (1-r) x_2) = 0$ when $r x_1 + (1-r) x_2 \leq s$, we obtain the convergence

$$V_\infty(x) = \lim_{d \to +\infty} V_d(x) = T(r x_1 + (1-r) x_2) .$$

Now, consider the domain $\mathcal{D}_\Delta = \{ s \in \mathbb{R}^2_+ \mid s_1 \geq s_2 > s \}$, and let us show that any trajectory of the optimal flow leaves $\mathcal{D}_\Delta$ at $(s, 2)$ with the help of this simple argumentation on the boundaries of the domain:

$$s_2 = s \Rightarrow \dot{s}_2 = \frac{d}{1-r} (s_1 - s) \geq 0 ,$$

$$s_1 = s_2 \Rightarrow \dot{s}_1 = \dot{s}_2 .$$

It is convenient to consider the variable $\dot{s} = rs_1 + (1-r)s_2$ whose optimal dynamics in $\mathcal{D}_\Delta$ are simply

$$\dot{s}(t) = -\gamma(s_1(t)) , \quad t \in [0, t_f] .$$
Because \( \tilde{s}(\cdot) \) is strictly decreasing with time, an optimal trajectory in \( D_+ \) can be parameterized by the fictitious time
\[
\tau(t) = rx_1 + (1 - r)x_2 - \tilde{s}(t) , \quad t \in [0, t_f]
\]
(5.5)
where \( x \) is an initial condition in \( D_+ \). The variable \( s_1(\cdot) \) is then a solution of the scalar nonautonomous dynamics
\[
\frac{ds_1}{d\tau} = f_d(\tau, s_1) = \begin{cases} 
- \frac{1}{r} - d\frac{s_1 + \tau - (rx_1 + (1 - r)x_2)}{r(1 - r)\gamma(s_1)} & \text{if } s_1 + \tau > rx_1 + (1 - r)x_2 , \\
1 & \text{if } s_1 + \tau = rx_1 + (1 - r)x_2 , 
\end{cases}
\]
with the terminal fictitious time
\[
\tau_f = rx_1 + (1 - r)x_2 - \tilde{s} .
\]
Notice that \( \tau_f \) is independent of \( d \). One then deduces the inequalities
\[
d_1 > d_2 \text{ and } s_1 + \tau > rx_1 + (1 - r)x_2 \implies f_{d_1}(\tau, s_1) < f_{d_2}(\tau, s_1)
\]
and thus,
\[
d_1 > d_2 \text{ and } x \in D_+ \setminus \Delta \implies s_1(x, u^*, d_1, \tau) < s_1(x, u^*, d_2, \tau) \quad \forall \tau \in [0, \tau_f] .
\]
Finally, from (5.4) and (5.5), the time to reach the target can be expressed as
\[
t_f = \int_0^{\tau_f} \frac{d\tau}{\gamma(s_1(\tau))} .
\]
(5.7)
Because the function \( \gamma(\cdot) \) is increasing and because \( \tau_f \) is independent of \( d \), one can conclude from (5.6) and (5.7) that
\[
d_1 > d_2 \text{ and } x \in D_+ \setminus \Delta \implies V_{d_1}(x) > V_{d_2}(x) .
\]
The case of initial conditions in \( D_- \setminus \Delta \), with \( D_- = \{ s \in \mathbb{R}^2_+ | s_2 \geq s_1 > \bar{s} \} \), is symmetric.

**Remark 4.** The tightness \( V_\infty - V_0 \) of the bounds on the value function \( V_d \) on \( (\bar{s}, +\infty)^2 \setminus \Delta \) is related to the concavity of the function \( T(\cdot) \) on \( (\bar{s}, +\infty) \) (the less the concavity \( \max_{\sigma \in (\bar{s}, +\infty)} T''(\sigma) \) is, the tighter the bounds are).

The bounds \( V_0 \leq V_d < V_\infty \) that are satisfied on the set \( (\bar{s}, +\infty)^2 \setminus \Delta \) are not necessarily satisfied outside this set: for \( x \) outside the target but such that \( rx_1 + (1 - r)x_2 < \bar{s} \) one has \( V_\infty(x) = 0 \) and \( V_0(x) > 0 \). Therefore, we conclude that a large diffusion negatively impacts the time to treat the resource when both zones are initially polluted; however, when one of the two zones is initially under the pollution threshold, a large diffusion could positively impact the duration of the treatment.

6. **Numerical illustrations.** We consider the Monod (or Michaelis–Menten) growth function, whose use is quite popular in bioprocesses and which satisfies Assumption 1,
\[
\mu(s) = \mu_{\max} \frac{s}{K_s + s}
\]
with the parameters \( \mu_{\max} = 1[h^{-1}] \) and \( K_s = 1[gL^{-1}] \). The corresponding function \( \gamma(\cdot) \) is depicted in Figure 2. The threshold that defines the target has been chosen as
MINIMAL TIME BIOREMEDIATION OF WATER RESOURCES

Fig. 2. Graphs of \( \mu(\cdot) \) and corresponding \( \gamma(\cdot) \).

Fig. 4. Level sets (in hours) of \( V_0 \) (left) and \( V_\infty \) (right) for \( r = 0.3 \).

\[ s = 1[gL^{-1}] \]. Several optimal trajectories in the phase portrait are drawn in Figure 3 for small and large values of the parameter \( d \). Finally, level sets of the value functions \( V_0 \) and \( V_\infty \) are represented in Figure 4. One can make the following observations concerning the influence of the diffusion on the treatment duration, that we consider to be valuable from a practical viewpoint.

- When pollution is homogeneous, it is best to maintain it as homogeneous, and the treatment time is then independent of the diffusion.
- A high diffusion is favorable for having fast treatments when initial concentrations are strongly different for the two zones. Typically, when the pollutant concentration is below the threshold in one patch, a high diffusion can reduce significantly the treatment time compared to a small diffusion.

- When initial concentrations in the two patches are close, a small diffusion leads to faster treatment than a large diffusion.

For various initial condition \( s(0) \), we have also performed numerical comparisons of the minimal time \( V_d(s(0)) \) given by the feedback strategy (4.1) against two other nonoptimal control strategies:

1. the best constant control that gives the smallest time \( T^*_{\text{opt}} \) to reach the target among constant controls;

2. the optimal one-pump feedback strategy obtained in the former work [14].

This last control strategy considers that only one patch can be treated (that we called the “active zone”). The problem amounts then to consider the same dynamics (2.5) but one seeks the feedback \( s^*_1(\cdot) \) that gives the minimal time \( T^*_{\text{one}} \) when \( \alpha \) is imposed to be constantly equal to 1 (or 0 depending which patch is treated). In [14], it has been proved that the feedback \( s_1 \mapsto s^*_1(s_1) \) is optimal.

The results presented in Table 1 show first that the benefit of using the optimal feedback strategy over the other strategies increases with the level of initial pollution. The simulations also demonstrate the gain of using two pumps instead of one: for large concentrations of pollutant at initial time, one can see on the tables that a constant two-pumps strategy can be even better that the optimal feedback strategy restricted to the use of one pump only. This kind of situation typically occurs when diffusion is low and the time required by the optimal strategy for using simultaneously the two pumps is large compared to the overall duration. This is particularly noticeable when the initial pollution is homogeneous and the use of two pumps allows us to maintain the levels of concentrations equal in both patches. We conclude that, for small diffusion, treating only one patch without the possibility of allocating the treatment in both
patches could be quite penalizing. Figure 5 illustrates the time history of the two feedback controllers.

Furthermore, Table 1 illustrates the effect of diffusion on the treatment times. One can first notice that the relative effect of the diffusion parameter $d$ on the optimal time $V_d$ is decreasing with the threshold $s$. This can be explained by the fact that the proportion of the time spent on the set $s_1 = s_2$, that is independent of the parameter $d$, is larger when one begins further away from the target. One can also see that the differences between strategies decrease when the diffusion increases. Intuitively, a high diffusion makes the resource behave quickly close to a perfectly mixed resource with one patch, leading consequently to less benefit of using more than one pump. Nevertheless, one can see that considering feedback controls remains quite efficient compared to constant ones when initial pollution is high.

Finally, we illustrate on Figure 6 the effect of approximating the original dynamics (2.4) by the reduced one (2.5), when applying the feedback (4.1). As proven in the appendix, the feedback (4.1) drives the state to the target in finite time for any $\epsilon > 0$.

7. Conclusion. In this work, we have shown that although the velocity set of the control problem is not convex, there exists an optimal solution with ordinary controls that is also optimal among relaxed controls. The optimal strategy consists in the most rapid approach to the homogenized concentration of pollutant in both patches. For the particular case of null diffusion, the most rapid approach path is not the unique solution of the problem. This optimal state feedback has some interesting features for the practitioners and controllers:

1. it does not require knowledge of the diffusion parameter $D$ to be implemented; and
2. if the ratio $r$ of the volumes of the two patches is not known, the optimal trajectory can be approximated by a regularization of the bang-bang control about the neighborhood of the set $s_1 = s_2$ that keeps the trajectory in this neighborhood.
Furthermore, has been shown in simulations that the benefit of using two pumps instead of one can be significant when the diffusion is low. We have also proposed explicit bounds on the minimal-time function, characterizing the extreme cases \( d = 0 \) and \( d = +\infty \). We have shown that a large diffusion rate increases the treatment time when the pollution concentration is above the desired threshold in both zones, while in contrast, it can be beneficial when the concentration in one of the two zones is below the desired threshold. This remarkable feature could serve practitioners in the choice of pump positioning in an originally clean water resource that is suddenly affected by a local pollution. Such an investigation could be the matter of future work.

**Appendix.** We give the proof of the following result.

**Proposition A.1.** For any \( \epsilon > 0 \), the feedback strategy (4.1) applied to the full dynamics (2.4) with \( x_r(0) > 0 \) drives the state to the target in finite time.

**Proof.** Without any loss of generality, we assume that \( s_1(0) \geq s_2(0) \) (the proof is similar when \( s_1(0) \leq s_2(0) \)).

If \( s_1(0) > s_2(0) \), we prove that \( s_1 = s_2 \) is reached in finite time. If not, one should have \( s_1(t) > s_2(t) \) with \( s_1(t) \geq \hat{s} \) for any \( t > 0 \). This implies having \( \alpha^*(t) = 1 \) and \( s_r^*(t) = \hat{s}(s_1(t)) \) at any time \( t > 0 \) and one has from (2.4),

\[
r \dot{s}_1 + (1 - r) \dot{s}_2 + \epsilon \dot{s}_r + \epsilon \dot{x}_r = -\epsilon \mu(s_r^*) x_r < 0 ,
\]

which implies that the trajectories are bounded. For any \( \sigma \geq \underline{s} \), \( \hat{s}_r^*(\sigma) \) being the unique maximizer of the function \( \beta(\sigma, \cdot) \), one has

\[
\sigma - \hat{s}_r^*(\sigma) = \frac{\mu(\hat{s}_r^*(\sigma))}{\mu'(\hat{s}_r^*(\sigma))}.
\]

The function \( \mu(\cdot) \) being increasing and concave, one obtains the inequality

\[
\sigma - \hat{s}_r^*(\sigma) \geq \eta := \frac{\mu(\hat{s}_r^*(\underline{s}))}{\mu'(\hat{s}_r^*(\underline{s}))} > 0 \quad \forall \sigma \geq \underline{s}.
\]

Furthermore, one can write

\[
r \dot{s}_1 + \epsilon \dot{s}_r = -d \epsilon (s_1 - s_2) - \mu(s_r) x_r < 0 .
\]
Thus $r s_1 + \epsilon s_t$ is decreasing and has a limit when $t$ tends to $+\infty$. Since the trajectories are bounded, $r s_1 + \epsilon s_t$ is uniformly continuous, and we conclude by Barbalat’s lemma (see, for instance, [16]) that $r s_1 + \epsilon s_t$ converges to 0, which implies that the positive quantities $s_1 - s_2$ and $\mu(s_t)x_t$ have to converge also to 0. Notice that $s_t = 0$ implies $\dot{s}_t = \mu(s_t) s_1 > \mu(s_t^*) s_2 > 0$. So $s_t$ cannot tend to 0 and $x_t$ has necessarily to converge to 0. Write now the dynamics
\[
\frac{d}{dt}(s_1 - s_t) = - \left(1 + \frac{\epsilon}{r}\right) \mu(s_t^*) (s_1 - s_t) - d_x(s_1 - s_2) - \mu(s_t)x_t,
\]
where $\mu(s_t^*) > \mu(s_t)$ and $d_x (s_1 - s_2) - \mu(s_t)x_t$ tends to 0. Thus, there exists a time $T > 0$ large enough such that
\[
s_t(t) > s_1(t) - \eta > s_t^*(t) \quad \forall t > T,
\]
which implies having $\mu(s_t) - \mu(s_t^*) > 0$ for large $t$, thus a contradiction with the convergence of $x_t$ to 0.

Clearly the feedback (4.1) leaves the set $\{s_1 = s_2\}$ invariant. Denote for simplicity $s_1 = s_1 = s_2$, and write
\[
\dot{s}_t + \epsilon \dot{s}_t + \epsilon \dot{x}_t = - \epsilon \mu(s_t^*)x_t < 0.
\]
Trajectories are thus bounded, and by Barbalat’s lemma one obtains that $\mu(s_t^*)x_t$ tends to 0. We prove now that $s_1$ has to reach s in finite time. If not, $\mu(s_t^*(t)) > \mu(s)$ for any time and $x_t$ tends to zero. Write the dynamics
\[
\frac{d}{dt}(s_1 - s_t) = -(1 + \epsilon) \mu(s_t^*) (s_1 - s_t) + \mu(s_t)x_t.
\]
As before, we deduce that there exists a time $T' > 0$ such that
\[
s_t(t) > s_1(t) - \eta > s_t^*(t) \quad \forall t > T',
\]
leading to a contradiction with the convergence of $x_t$ to 0.
