Otto Warburg suggested that cancer originates from irreversible injury to mitochondria followed by a compensatory increase in glycolysis. Nevertheless, increasing evidence indicates that mitochondrial metabolism is an essential component of most cancer cells and serves as a source of metabolic intermediates for lipid, nucleic acid, and protein synthesis.\(^1\) \(\text{Ca}^{2+}\) release from the endoplasmic reticulum (ER) through the inositol 1,4,5-trisphosphate receptors (InsP\(_3\)Rs) regulates numerous cellular functions including gene transcription, cell proliferation, secretion, and motility.\(^2\) Recently, we established that low-level constitutive InsP\(_3\)R-mediated \(\text{Ca}^{2+}\) transfer to the mitochondria is essential for maintaining basal levels of oxidative phosphorylation (OXPHOS) and ATP production (Fig. 1) in a wide variety of cell types.\(^3\) Agonist-induced InsP\(_3\)R \(\text{Ca}^{2+}\) signals enhance mitochondrial function primarily by stimulating the tricarboxylic acid (TCA) cycle dehydrogenases, as well as respiratory chain components, to promote OXPHOS and ATP production.\(^4\) In the absence of InsP\(_3\)R-mediated \(\text{Ca}^{2+}\) transfer to mitochondria, cells enter a bioenergetic crisis characterized by a drop in ATP levels, AMPK activation, and induction of mTOR-independent autophagy as an essential survival mechanism.\(^5\) (Fig. 1) The \(\text{Ca}^{2+}\) released by InsP\(_3\)Rs is taken up by mitochondria via the \(\text{Ca}^{2+}\) uniporter (MCU), an inner membrane \(\text{Ca}^{2+}\) channel whose molecular identity has recently been revealed.\(^5\) The MCU channel is a complex (MCUC) composed of several proteins that regulate its activity, including MUCUB, EMRE, MUCUR1, MICU1, and MICU2.\(^5\) We found that inhibition of mitochondrial \(\text{Ca}^{2+}\) uptake by knockdown of \(\text{MCU}\) or \(\text{MCUR1}\) recapitulates the bioenergetic features observed after InsP\(_3\)R inhibition, namely a decrease in ATP levels, AMPK activation, and induction of prosurvival autophagy (Fig. 1).\(^6,7\) thus confirming the essential role of \(\text{Ca}^{2+}\) communication between the ER and the mitochondria for cellular homeostasis.

Although increased InsP\(_3\)R expression and/or activity have been associated with cancer cell proliferation and growth, how InsP\(_3\)Rs regulate these processes was unknown. Using breast and prostate tumorigenic cell lines and transformed primary human fibroblasts, we discovered that cancer cells also require low-level constitutive InsP\(_3\)R-mediated \(\text{Ca}^{2+}\) transfer to mitochondria to sustain mitochondrial function.\(^8\) Genetic or pharmacological inhibition of either InsP\(_3\)R or MCUC in these cells decreases TCA cycle activity, with a concomitant reduction in the levels of ATP and metabolic intermediates, and activation of AMPK and autophagy. Interestingly, whereas non-cancerous cells are able to survive under these conditions through autophagy, cancer cells die by necrosis at the stage of daughter cell separation during proliferation.\(^8\) All the metabolic effects observed due to interruption of ER-to-mitochondria calcium transfer in both normal and cancer cells, as well as the death of cancer cells, were reversed by exogenous addition of the mitochondrial substrates pyruvate or \(\alpha\)-ketoglutarate. This protection was unrelated to antioxidant properties of the substrates since NAC was unable to prevent either the metabolic effects or cell death.\(^8\) Although AMPK activation in the cancer cells indicates lower ATP levels after inhibition of InsP\(_3\)R-mediated \(\text{Ca}^{2+}\) transfer to mitochondria, much evidence suggests that glycolysis is able to provide enough ATP for cancer cell function.\(^9\) Thus, we speculated that in addition to the effects of this \(\text{Ca}^{2+}\) transfer on OXPHOS, other mitochondrial functions contribute to the apparent addiction of cancer cells to \(\text{Ca}^{2+}\). Considering that at least 3 mitochondrial pathways are involved in pyrimidine and purine nucleotide synthesis and that the rate-limiting step in the \textit{de novo} synthesis of pyrimidines occurs in the mitochondria,\(^10\) we speculated that a lack of metabolic intermediates, in particular nucleotides, is responsible for the observed death of cancer cells. Indeed, nucleoside complementation prevented cancer cell death. Normal cells facing the
metabolic stress induced by inhibiting InsP₃R-mediated Ca²⁺ transfer to mitochondria reduced their proliferation by slowing cell cycle progression at the G1/S checkpoint, whereas cancer cells continued to enter the cell cycle regardless of their impaired bioenergetic and metabolic state, leading to death by necrosis at the last step of mitosis (Fig. 1). Treatment of tumors generated by subcutaneous injection of murine melanoma derived B16F10 cells into nude mice with the InsP₃R inhibitor Xestospongin B caused marked inhibition of tumor growth associated with massive necrotic cell death without changes in the levels of Ki67, a marker of proliferation, confirming that the cancer cells failed to slow cell growth in the face of their bioenergetic crisis because of a failure to either “monitor” their metabolic status or to engage cell cycle checkpoints, or both. Cell proliferation requires new protein, lipid, and nucleic acid synthesis, and although the interactions between metabolism and the cell cycle are becoming increasingly revealed, our understanding of the molecular wiring that links these processes remains incomplete. Our recent work suggests that inhibition of ER-to-mitochondria Ca²⁺ transfer uncouples these 2 processes in cancer cells, turning their high proliferative rate, a normally advantageous feature, into a mechanism that promotes their death.

In summary, our recent study suggests that cancer cells are addicted to InsP₃R-mediated Ca²⁺ transfer to mitochondria, and therefore implicates possible therapeutic targets.
