ABSTRACT

Aims. We present here a follow-up study of the molecular gas and dust in the environs of the star forming region NGC 3503. This study aims at dealing with the interaction of the H II region NGC 3503 with its parental molecular cloud, and also with the star formation in the region, that was possibly triggered by the expansion of the ionization front against the parental cloud.
Methods. To analyze the molecular gas we use $CO(J = 2 \rightarrow 1)$, $^{13}CO(J = 2 \rightarrow 1)$, $C^{18}O(J = 2 \rightarrow 1)$, and $HCN(J = 3 \rightarrow 2)$ line data obtained with the on-the-fly technique from the APEX telescope. To study the distribution of the dust, we make use of unpublished images at 870 μm from the ATLASGAL survey and IRAC-GLIMPSE archival images. We use public 2MASS and WISE data to search for infrared candidate young stellar objects (YSOs) in the region.
Results. The new APEX observations allowed the substructure of the molecular gas in the velocity range from ~-28 km s^{-1} to -23 km s^{-1} to be imaged in detail. The morphology of the molecular gas close to the nebula, the location of the PDR, and the shape of radio continuum emission suggest that the ionized gas is expanding against its parental cloud, and confirm the champagne flow scenario. We have identified several molecular clumps and determined some of their physical and dynamical properties such as density, excitation temperature, mass, and line width. Clumps adjacent to the ionization front are expected to be affected by the H II region, unlike those that are distant from it. We have compared the physical properties of the two kinds of clumps to investigate how the molecular gas has been affected by the H II region. Clumps adjacent to the ionization fronts of NGC 3503 and/or the bright rimmed cloud SFO 62 have been heated and compressed by the ionized gas, but their line width is not different from those that are too distant from the ionization fronts. We identified several candidate YSOs in the region. Their spatial distribution suggests that stellar formation might have been boosted by the expansion of the nebula. We discard the collect-and-collapse scenario and propose alternative mechanisms such as radiatively driven implosion on pre-existing molecular clumps or small-scale Jeans gravitational instabilities.

Key words. stars: formation – HII regions – ISM: molecules – ISM: individual objects: NGC 3503

1. Introduction

It is accepted that OB associations have an enormous impact on the state of their environs. The interstellar medium (ISM) surrounding OB stars is expected to be strongly modified and disturbed by their intense ultraviolet (UV) radiation field ($h\nu > 13.6$ eV). Ultraviolet photons ionize the surrounding gas creating H II regions; they also dissociate the molecular gas originating photodissociation regions (PDRs) (Hollenbach & Tielens 1997). In addition, the surrounding neutral gas (either atomic or molecular), is compressed by the expansion of the H II region and/or the action of stellar winds. The compression of the cloud could enhance the stellar formation via radiative driven implosion process (RDI; Lefloch & Lazareff 1994) or even trigger it via the collect-and-collapse process (Elmegreen & Lada 1977). Therefore, when massive stars form inside a molecular cloud it is expected that they dominate the state of the parental cloud and consequently the stellar formation process within. It has been shown that a large fraction of stars originate at the peripheries of H II regions (Pomarès et al. 2009; Romero & Cappa 2009; Cappa et al. 2009; Deharveng et al. 2010, 2012; Vasquez et al. 2012).

Keeping this in mind, it is instructive to study the molecular gas adjacent to H II regions since it can provide important information on the interaction between massive stars and their natal environments. Furthermore, a comparison between regions of the molecular cloud adjacent to an H II region with other sites far from it may provide significant understanding into the physical properties of the molecular gas that may affect the formation of stars.

The optical emission nebula NGC 3503 (=Hf 44 = BBW 335) is a small H II region located at RA, Dec (J2000) = ($11^h01^m16^s$, $-59°50'39''$) (Dreyer & Sinnott 1988), and placed at a distance of 2.9 ± 0.4 kpc (Pinheiro et al. 2010). The source is ionized by early B-type stars belonging to the open cluster Pis 17 (Herbst 1975; Pinheiro et al. 2010; Duronea et al. 2012) and is believed to be related to the bright-rimmed cloud (BRC) SFO 62 (Sugitani et al. 1991; Yamaguchi et al. 1999; Thompson et al. 2004; Urquhart et al. 2009), although the ionizing star/s of the BRC have not been identified with certainty. In a recent work (Duronea et al. 2012; hereafter Paper I), we carried out a multifrequency analysis in the environs of NGC 3503. We analyzed the properties of the molecular gas using NANTEN ^{12}CO ($J = 1 \rightarrow 0$) ($HPBW = 2.'7$) observations, while the ionized gas was studied making use of radio continuum observations at 4800 MHz and 8640 MHz, with synthesized beams

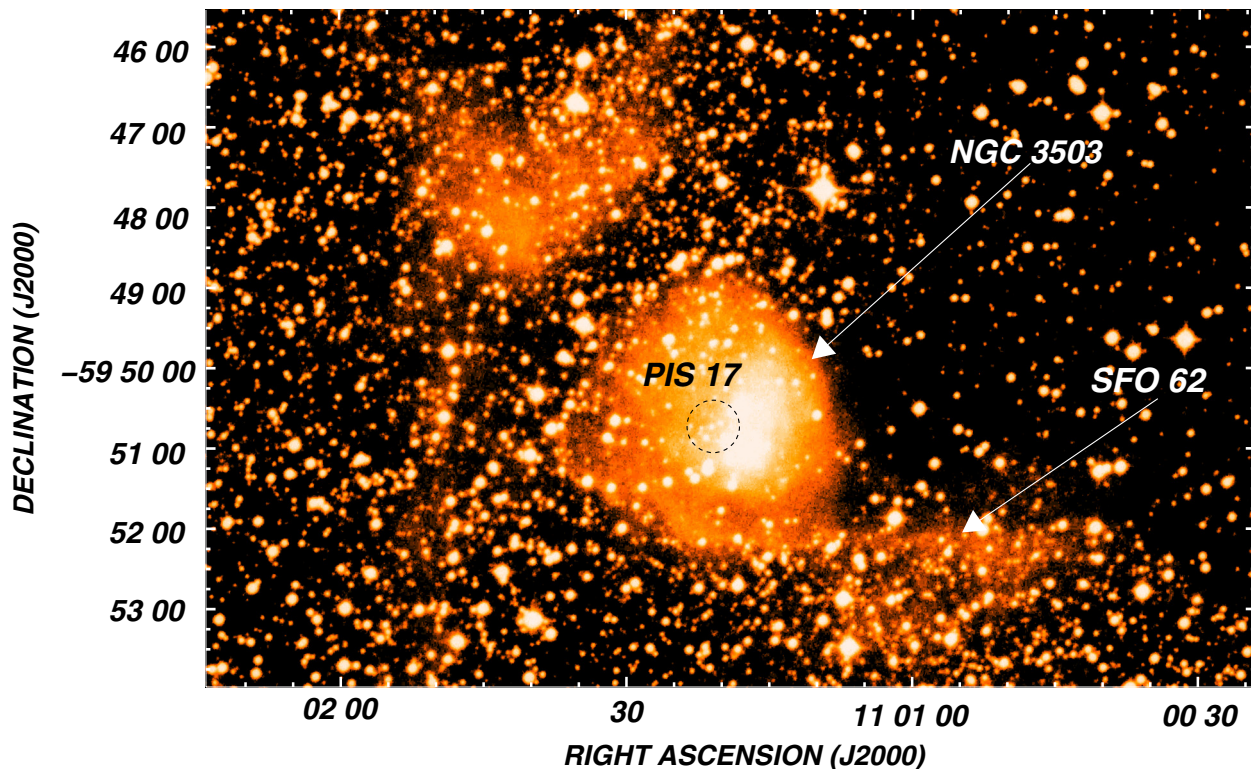

Fig. 1. UKST red plate image of the nebula NGC 3503 in the area covered by the APEX data. The positions of NGC 3503, the bright rimmed cloud SFO 62 , and the open cluster Pis 17 are indicated.

of $23''55 \times 18''62$ and $14''73 \times 11''74$, respectively, carried out with ATCA. The molecular line observations revealed a molecular gas component of 7.6×10^3 $M_\odot$ in mass having a mean radial velocity[1] of -24.7 km s^{-1} (in agreement with the velocity of the ionized gas of NGC 3503; Georgelin et al. 2000), which is associated with the nebula and its surroundings. We reported an overdensity centered at RA, Dec (J2000) = ($11^h01^m02.48^s$, $-59°50'04.6''$ ($l, b = 289°.47, +0°.12$) (clump A) projected near the border of NGC 3503, which is physically related to the nebula. Radio continuum images suggest that the highest electron density area in the H II region (coincident with the ionization front) is compressing the densest part of the molecular overdensity, while the low electron density region is undergoing a champagne phase. Three compact MSX H II region (CH II) candidates were also reported lying at the inner border of the nebula, which confirm the mentioned scenario (see Fig. 2). In spite of the strong evidence of interaction between NGC 3503 and its molecular environment, disparities in angular resolution made a direct comparison between molecular and radio continuum/IR images difficult. Furthermore, the low angular resolution of the CO data did not allow us to detect any substructure in the molecular gas associated with NGC 3503, and therefore a detailed analysis could not be done adequately.

The analysis of the molecular gas and dust associated with NGC 3503 presents an important opportunity to study the interactions between H II regions with molecular clouds, and how the formation of massive stars (Pis 17) in the cloud can affect further (or ongoing) star formation.

In this paper, we present new CO($J = 2 \rightarrow 1$), ^{13}CO($J = 2 \rightarrow 1$), C^{18}O($J = 2 \rightarrow 1$), and HCN($J = 3 \rightarrow 2$) observations around the H II region NGC 3503 carried out with the Atacama

Pathfinder Experiment (APEX) 12 m telescope[2]. To account for the properties of the dust in the nebula and its surroundings, we use unpublished images at 870 μm from the APEX Telescope Large Area Survey of the Galaxy (ATLASGAL). The aim of this work is to investigate in detail the spatial distribution and physical characteristics of the molecular gas and dust associated with NGC 3503, and to compare them with the different gas components observed with similar angular resolutions. This analysis will also allow us to identify regions of dense molecular gas where star formation may be developing. To look for signatures of star formation, a new discussion of young stellar object (YSO) candidates in the surroundings of NGC 3503 using archival data of Wide-field Infrared Survey Explorer (WISE) and Two Micron All Sky Survey (2MASS) is also presented. In Fig. 1 we show the UK Schmidt Telescope (UKST) red image[3] of the area of the nebula NGC 3503 surveyed by our molecular observations.

2. Observations

2.1. Molecular observations

The molecular observations presented in this paper were made during October 2011, with APEX (Güsten et al. 2006) at Llano de Chajnantor (Chilean Andes). As front end for the observations, we used the APEX-1 receiver of the Swedish Heterodyne Facility Instrument (SHeFI; Vassilev et al. 2008). The back end for all observations was the eXtended bandwidth Fast Fourier Transform Spectrometer2 (XFFTS2) with a 2.5 GHz bandwidth

---

[1] Radial velocities in this paper always refer to the local standard of rest (LSR).

[2] APEX is a collaboration among the Max-Planck-Institut fur Radioastronomie, the European Southern Observatory, and the Onsala Space Observatory.

[3] http://www-wfau.roe.ac.uk/sss/index.html

Table 1. Observational parameters for the observed transitions.

Molecular transition	Frequency (GHz)	Beam ($''$)	Velocity resolution (km s^{-1})	rms noise (K)
CO($J = 2 \rightarrow 1$)	230.538000	~27	0.099	~0.3
^{13}CO($J = 2 \rightarrow 1$)	220.398677	~28	0.104	~0.3
C^{18}O($J = 2 \rightarrow 1$)	219.560357	~28	0.150	~0.25
HCN($J = 3 \rightarrow 2$)	265.886180	~23	0.086	~0.4

divided into 32 768 channels. The observed transitions and basic observational parameters are summarized in Table 1. Calibration was done by the chopper-wheel technique, and the output intensity scale given by the system is T_A, which represents the antenna temperature corrected for atmospheric attenuation. The observed intensities were converted to the main-beam brightness temperature scale by $T_{mb} = T_A/\eta_{mb}$, where η_{mb} is the main beam efficiency. For the SHeFI/APEX-1 receiver we adopt $\eta_{mb} = 0.75$.

Observations were made using the on-the-fly (OTF) mode with two orthogonal scan directions along RA and Dec (J2000) centered on RA, Dec (J2000)= ($11^h01^m16^s$, $-59°50'39''$). For the observations we mapped a region of ~$15' \times 10'$. The spectra were reduced using the CLASS90 programme of the IRAM GILDAS software package[4].

2.2. Continuum dust observations

In this work we use unpublished images of ATLASGAL at 870 μm (345 GHz) (Schuller et al. 2009). This survey covers the inner Galactic plane, $l = 300°$ to $60°$, $|b| \leq 1°5$, with a rms noise in the range $0.05-0.07$ Jy beam^{-1}. The calibration uncertainty in the final maps is about of 15%. The Large APEX BOlometer CAmera (LABOCA) used for these observations, is a 295-pixel bolometer array developed by the Max-Planck-Institut fur Radioastronomie (Siringo et al. 2007). The beam size at 870 μm is 19$.''$2. The observations were reduced using the Bolometer array data Analysis package (BoA; Schuller 2012).

2.3. Physical parameter estimations

2.3.1. Excitation temperature and opacity

Excitation temperature (T_{exc}) and opacity (τ) of the CO($J = 2 \rightarrow 1$) and ^{13}CO($J = 2 \rightarrow 1$) lines in local thermodynamic equilibrium (LTE) conditions, can be derived using

$$T_{peak} = T_0 [J(T_{exc}) - J(T_{bg})] \times [1 - e^{(-\tau)}] \quad (1)$$

(Dickman 1978), where $T_0 = h\nu/k$, $J(T) = (e^{T_0/T} - 1)^{-1}$, and T_{bg} is the background temperature (assumed to be ~2.7 K). The excitation temperature of the ^{13}CO($J = 2 \rightarrow 1$) line can be derived adopting $T_{exc}(^{13}$CO$) \approx T_{exc}($CO$)$, which can be calculated assuming that $\tau^{12} \gg 1$ and solving Eq. (1) as

$$T_{exc}(\text{CO}) = \frac{T_0^{12}}{\ln\left[1 + \frac{T_0^{12}}{T_{peak}(\text{CO}) + T_0^{12} \; [e^{(T_0^{12}/T_{bg})}-1]^{-1}}\right]}, \quad (2)$$

where $T_0^{12} = h\nu^{12}/k$, with $\nu^{12} = 230.538$ GHz for the CO($J = 2 \rightarrow 1$) line. Then, the opacity of the ^{13}CO($J = 2 \rightarrow 1$) line can

[4] http://www.iram.fr/IRAMFR/GILDAS

be derived solving again Eq. (1),

$$\tau^{13} = -\ln\left[1 - \left(T_{mb}^{13}/T_0^{13}\right)\left[\left(e^{T_0^{13}/T_{exc}} - 1\right)^{-1} - \left(e^{(T_0^{13}/T_{bg})} - 1\right)^{-1}\right]^{-1}\right], \quad (3)$$

where $T_0^{13} = h\nu^{13}/k$, with $\nu^{13} = 220.399$ GHz. We can also estimate the optical depth of the CO($J = 2 \rightarrow 1$) line from the ^{13}CO($J = 2 \rightarrow 1$) line with

$$\tau^{12} = \left[\frac{\nu^{13}}{\nu^{12}}\right]^2 \left[\frac{\Delta v^{13}}{\Delta v^{12}}\right] \left[\frac{\text{CO}}{^{13}\text{CO}}\right] \tau^{13}, \quad (4)$$

where CO/^{13}CO is the isotope ratio (assumed to be ~62; Langer & Penzias 1993); Δv^{13} and Δv^{12} are defined as the *full width half maximum* (FWHM) of the spectrum of the ^{13}CO and CO lines, respectively, which are derived by using a single Gaussian fitting ($FWHM = 2 \times \sqrt{2 \ln 2} \times \sigma_{Gauss}$).

2.3.2. Column density and mass

Assuming LTE conditions the H$_2$ column density, N(H$_2$), can be estimated from the ^{13}CO($J = 2 \rightarrow 1$) line following the equations of Rohlfs & Wilson (2004)

$$N(^{13}\text{CO}) = 1.5 \times 10^{14} \; \frac{e^{[T_0(\nu_{10})/T_{exc}]} \; T_{exc} \int \tau^{13} \; dv}{1 - e^{[-T_0^{13}/T_{exc}]}} \quad (\text{cm}^{-2}), \quad (5)$$

where $T_0(\nu_{10}) = h\nu_{10}/k$, being ν_{10} the frequency of the ^{13}CO ($1 \rightarrow 0$) line (110.201 GHz). To solve the integral of Eq. (5) it can be assumed (in the limit of an optically thin line) that $T_{exc} \tau^{13} \approx T_{mb}$. Nevertheless, optical depth effects can be diminished using the approximation

$$T_{exc} \int \tau^{13} dv \approx [\tau^{13}/1 - e^{(-\tau^{13})}] \int T_{mb} \; dv. \quad (6)$$

This formula is accurate to 15% for $\tau^{13} < 2$. We also estimate an uncertainty of ~20% from determining $\int T_{mb} \; dv$. The molecular mass is then calculated using

$$M(\text{H}_2) = m_{sun}^{-1} \; \mu \; m_H \; \sum \; \Omega \; N(\text{H}_2) \; d^2 \quad (M_\odot), \quad (7)$$

where m_{sun} is the solar mass (~2×10^{33} g); μ is the mean molecular weight, which is assumed to be equal to 2.72 after allowance of a relative helium abundance of 25% by mass (Allen 1973); m_H is the hydrogen atom mass (~1.67×10^{-24} g); Ω is the solid angle subtended by the CO feature in ster; d is the distance (assumed to be 2.9 ± 0.4 kpc; see Paper I) expressed in cm; and N(H$_2$) is obtained using a canonical abundance N(H$_2$)/$N(^{13}$CO$) = 5 \times 10^5$ (Dickman 1978).

Considering only gravitational and internal pressure, neglecting support of magnetic fields or internal heating sources, and assuming a spherically symmetric cloud with a r^{-2} density distribution, the virialized molecular mass, M_{vir}, can be estimated from

$$M_{vir} = 126 \, R_{eff} \, (\Delta v_{cld})^2 \quad (M_\odot) \quad (8)$$

(MacLaren et al. 1988), where $R_{eff} = \sqrt{A_{cloud}/\pi}$ is the effective radius in parsecs, and Δv_{cld} is the width of the composite spectrum, defined as for Δv^{13} and Δv^{12} in Eq. (4). The composite spectrum is obtained by averaging all the spectra within the area of the cloud (A_{cloud}).
Fig. 2. Composite image of NGC 3503 and its environs. Red and green show emission at 8.0 and 4.5 μm (IRAC-GLIMPSE), respectively. White and blue contours show the radio continuum 4800 MHz and integrated CO line emissions. Circles in light blue indicate the position of the three candidates to compact H II region identified using the MSX Catalog (see Table 3 in Paper I). The CO temperature contours are 0.5 K km s^{-1} ($\sim$10 rms), 1.5, 6.6, 10.5, 15.5, 20.5, 25.5, and 30.5 K km s^{-1}. The radio continuum 4800 MHz contours levels go from 2.4 mJy beam^{-1} ($\sim$3 rms) to 10.4 mJy beam^{-1} in steps of 2 mJy beam^{-1}, and from 10.4 mJy beam^{-1} in steps of 4 mJy beam^{-1}.

The mass of the dust can be calculated following Deharveng et al. (2009). Considering that the emission detected at 870 μm originates in thermal dust emission, the dust mass (M_{dust}) can be derived from

$$M_{dust} = \frac{S_{870}\, d^2}{\kappa_{870}\, J_{870}(T_{dust})}, \qquad (9)$$

where S_{870} is the measured flux density, d is the adopted distance to the source, κ_{870} is the dust opacity per unit mass at 870 μm, and $J_{870}(T_{dust})$ is the Planck function for a temperature T_{dust}. We adopted a dust opacity $\kappa_{870} = 1.0$ cm^2 g^{-1} estimated for dust grains with thin ice mantles in cold clumps (Ossenkopf & Henning 1994).

3. Results and analysis of the observations

3.1. Spatial distribution of the molecular gas

To study the molecular gas associated with NGC 3503 we have mostly focused on Component 1 of Paper I (which is undoubtedly associated with the nebula). We will also make a brief analysis of the molecular gas associated with Component 2 and Component 3.

In Fig. 2 we show an overlay of the mean CO emission as obtained with APEX, in the velocity interval from -29 km s^{-1} to -24 km s^{-1}, onto the IRAC-GLIMPSE[5] (Benjamin et al. 2003) and 4800 MHz radio continuum emission[6] of the nebula.

[5] http://sha.ipac.caltech.edu/applications/Spitzer/SHA/
[6] Obtained with ATCA (see Paper I).

Although a remarkable resemblance between CO and IR emission (MSX-A band) was previously put forward in Paper I, especially towards the extended IR emission to the north and east of NGC 3503 (see Fig. 6 of that work), a tight morphological correlation between the IR nebula and the molecular gas in the studied velocity interval is revealed by our new APEX observations, which confirms that this cloud is physically associated with the IR nebula. From Fig. 2, a direct comparison of the molecular and 4800 MHz radio continuum emissions strongly suggests that the molecular gas is being compressed by an ionization front and is interacting with the nebula. On the other hand, the ionized gas seems to be expanding freely towards the opposite direction (i.e. the intercloud medium). The location of the PDR is traced by the emission of PAHs molecules in the 8.0 μm image (shown in red). Since these complex molecules are destroyed inside the ionized gas of an H II region (see Deharveng et al. 2010, and references therein), they delineate the boundaries of NGC 3503. The molecular gas clearly depicts the position of the ionization front. As predicted in Paper I, no molecular emission is detected in this velocity range towards the low electron density region, which is compatible with a champagne-flow scenario. However, we speculate that the IR arc-like filament (from here onwards called the IR arc) seen in the northeastern border of the nebula at RA, Dec (J2000) $\sim$ (11^{h}01^{m}30^s, $-59°50'10''$) and RA, Dec (J2000) $\sim$ (11^{h}01^{m}25^s, $-59°49'00''$), might be still associated with small amounts of molecular gas at velocities between ~-17.1 km s^{-1} and -15.3 km s^{-1} (see Sect. 3.2).

Since the CO($J = 2 \rightarrow 1$) line is optically thick and can be used only to trace low density gas, we analyze the ^{13}CO data which allows one to go deeper into the molecular
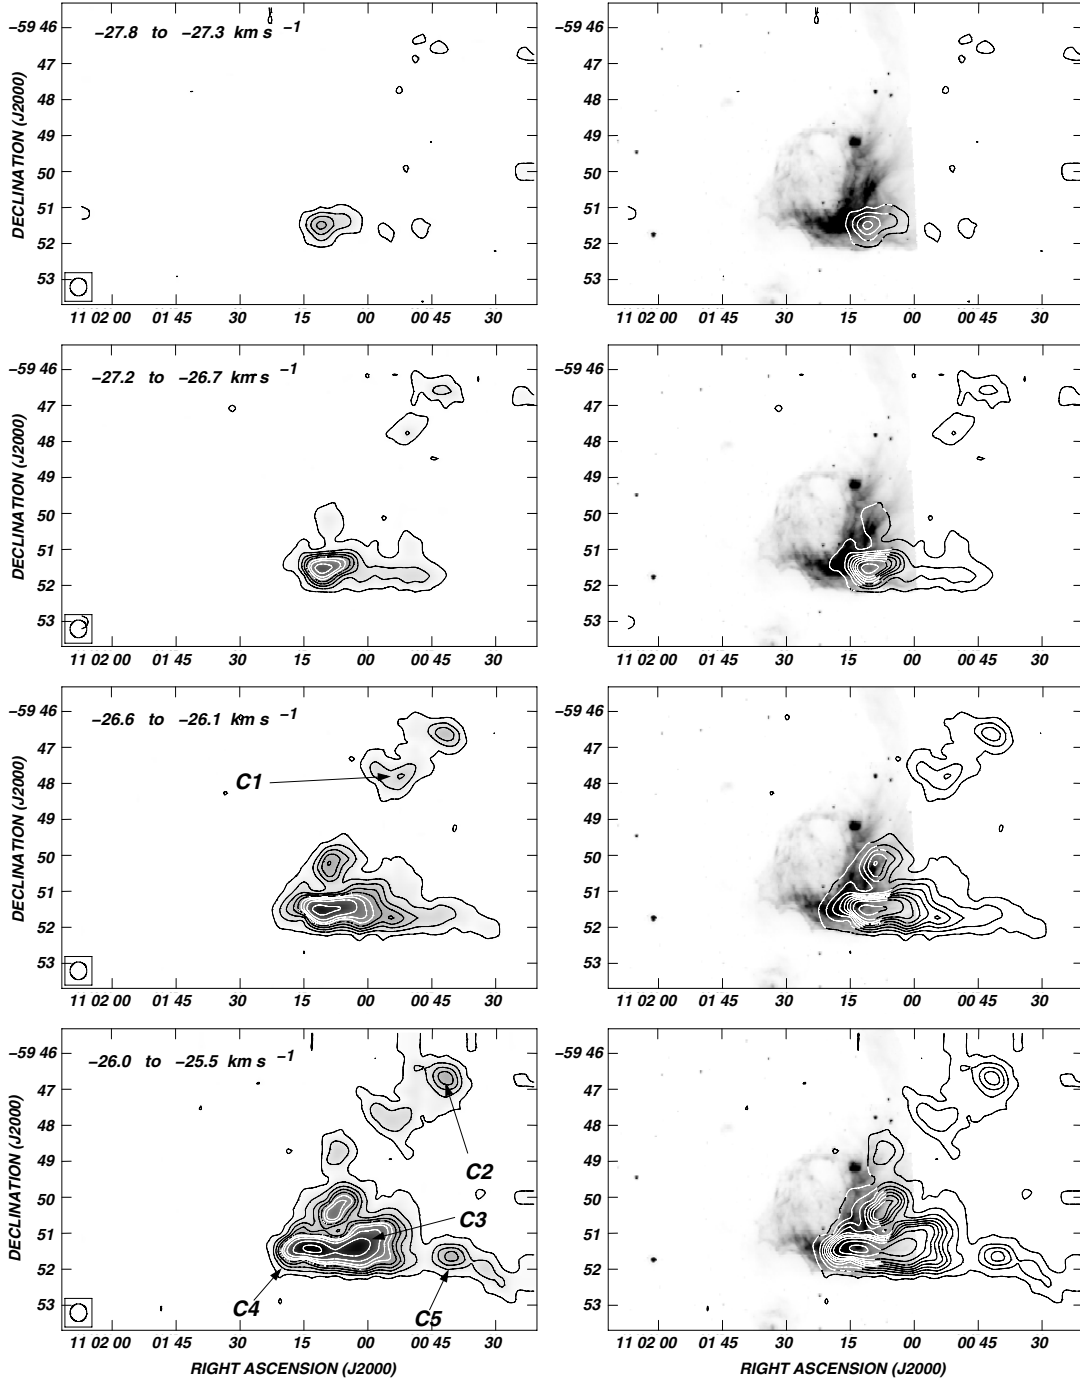

Fig. 3. *Left panels*: integrated ^{13}CO emission in the velocity range from ~ -27.8 km s^{-1} to -23.7 km s^{-1}, and from 18.7 km s^{-1} to 21.7 km s^{-1} (see continuation). The velocity interval of each image is indicated in the upper-left corner. The lowest temperature contour is 0.7 K km s^{-1} ($\sim$5 rms). The contour spacing temperature is 1.5 K km s^{-1} to 9.7 K km s^{-1}, and then 4 K km s^{-1}. The beam size is shown by a circle in the lower-left corner of each image. *Right panels*: overlay of the IRAC GLIMPSE 4 (8 μm) emission of NGC 3503 (grayscale) and the mean ^{13}CO emission in the velocity intervals shown in the *left panels* (contour lines).

clouds, although it may fail to probe the densest molecular gas because it freezes onto dust grains at high densities (Massi et al. 2007). To study the kinematics of the molecular gas in more detail we have averaged the individual original channel maps of the ^{13}CO emission line. In Fig. 3 (left panels) we show a collection of narrow velocity images depicting the mean ^{13}CO spatial distribution in the velocity range from -27.8 km s^{-1} to -23.7 km s^{-1}. Every image represents an integral of the ^{13}CO emission $\int T_{\rm mb}\, dv$ (K km s^{-1}) over a velocity interval of 0.5 km s^{-1}. In this way, the final rms noise for each interval

results $\Delta T_{\rm rms} \approx 0.15$ K km s^{-1}. To analyze the relation between the molecular gas and the warm dust in the nebula, in the right panels of Fig. 3 we show the ^{13}CO emission in the velocity intervals mentioned before (in contours) projected onto the IRAC GLIMPSE-4 (8 μm) emission of NGC 3503 (grayscale). In order to study the small-scale structure of the molecular cloud we have identified a number of small molecular clumps. The clumps were selected by eye and based on the following simplest criteria: 1) the peak temperature of each clump is at least 5 times the rms noise; 2) the decrease in $T_{\rm mb}$ between the peak temperature

**Fig. 3.** continued.

of two adjacent clumps is larger than 5 times the rms noise; and 3) the clump is present at least along ~40% of the total velocity interval of the cloud. We define the area of each clump (A_{clump}) by the polygon that encloses the emission corresponding to half the T_{mb} peak in the velocity interval at which the clump is observed. The clumps are indicated in Fig. 3 from C1 to C8 and the labeling was made in the velocity interval at which they reach the maximum emission peak temperature. These molecular clumps are also identified in CO showing more extended emission.

The molecular emission becomes noticeable first in the velocity interval from -27.8 km s^{-1} to -27.3 km s^{-1} as a weak patchy structure centered at (RA, Dec (J2000)) $\simeq$ (11^{h}01^{m}10^s, $-59°51'30''$). Within the velocity range from -27.2 km s^{-1} to -26.7 km s^{-1} most of the emission comes from a broad and cometary head-tailed structure lying along Dec (J2000) $\approx$ $-59°51'30''$ that is coincident with the optical feature SFO 62 (see Fig. 1). This coincidence might confirm that this molecular feature is being ionized from a stellar source (or sources) at lower declinations giving rise to the BRC, as previously suggested in Paper I. This structure shows a sharp cutoff in the direction of NGC 3503 which suggests an interaction between the HII region and the molecular gas. Very likely, the molecular gas has undergone compression on the front side as a result

of the expansion of the ionized gas and/or the stellar winds of members of Pis 17. This trend is also observed in the CO emission. Between -26.6 km s^{-1} and -26.1 km s^{-1} a molecular emission maximum, detected close to the brightest IR region of NGC 3503 at (RA, Dec (J2000)) $\approx$ (11^{h}01^{m}15^s, $-59°51'25''$), appears to be merged with the lengthened molecular structure along Dec (J2000) $\approx$ $-59°51'30''$. A molecular clump, C1, is indicated in this velocity interval, located at (RA, Dec (J2000)) $\approx$ (11^{h}00^{m}50^s, $-59°47'57''$). This clump is detected in the total velocity range from -27.1 km s^{-1} to -25.6 km s^{-1}.

In the velocity range from -26.0 km s^{-1} to -25.5 km s^{-1} the molecular emission shows a good morphological resemblance with the IR nebula. Four molecular clumps achieve their maximum emission temperature at this velocity range. Clump C2 is placed adjacent to C1, at (RA, Dec (J2000)) $\approx$ (11^{h}00^{m}40^s, $-59°46'40''$) and is identifiable in the total velocity range from -27.3 km s^{-1} to -24.3 km s^{-1}. A moderately intense extended emission seems to be connecting both clumps, which may indicate a physical association. Clumps C3 and C4 are located at (RA, Dec (J2000)) $\approx$ (11^{h}01^{m}05^s, $-59°51'30''$) and (RA, Dec (J2000)) $\approx$ (11^{h}01^{m}12^s, $-59°51'25''$), respectively. Their locations are coincident with the cometary head-tailed feature observed between -27.2 km s^{-1} and -26.7 km s^{-1} which
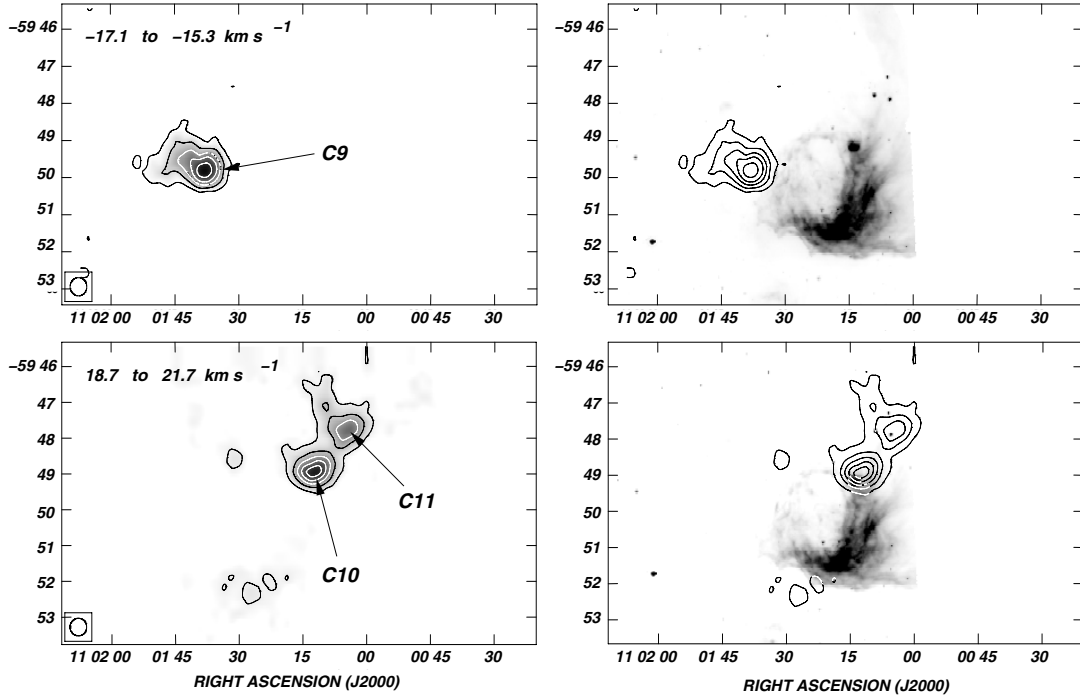

Fig. 4. *Left panels*: integrated ^{13}CO emission in the velocity range from ∼−17.1 km s^{-1} to −15.3 km s^{-1} (*upper panel*), and from 18.7 km s^{-1} to 21.7 km s^{-1} (*lower panel*). The velocity interval of each image is indicated in the upper-left corner. In *the upper panel*, the lowest ^{13}CO temperature contour is 0.35 K km s^{-1} (∼5 rms) and the contour spacing temperature is 0.7 K km s^{-1}. In *the lower panels*, the lowest ^{13}CO temperature contour is 0.75 K km s^{-1} (∼15 rms) and contour spacing temperature is 1 K km s^{-1}. The beam size is shown by a circle in the lower-left corner of each image. *Right panels*: overlay of the IRAC GLIMPSE 4 (8 μm) emission of NGC 3503 (grayscale) and the mean ^{13}CO emission in the velocity intervals shown in the *left panels* (contour lines).

means that they all are part of the same molecular structure. This correlation suggests that the formation of clumps C3 and C4 is the result of a fragmentation due to the compression of the H II region (Whitworth et al. 1994), although previous estimates seem to discredit this conjecture (see Paper I). The molecular emission in the direction of these clumps is detected almost in the entire velocity range. The position of C4 is highly coincident with an MSX compact H II region candidate labeled as source 3 in Paper I (see Fig. 2). This suggests that C4 is a high-density molecular clump that has been irradiated by the UV field of NGC 3503. The fourth molecular clump detected in this velocity range, C5, is located at (RA, Dec (J2000)) ≈ (11^{h}00^{m}40^s, −59°51′30″). Its location is almost adjacent with the western-most border of SFO 62 (see Fig. 1) and its eastern border seems to be connected with the western side of C3 by a weak bridge of ^{13}CO emission. The molecular emission of C5 is detectable up to −24.9 km s^{-1}. Clumps C3, C4, and C5 are detected in the total velocity range from −27.1 km s^{-1} to −24.9 km s^{-1}, −27.8 km s^{-1} to −24.5 km s^{-1}, and −26.6 km s^{-1} to −24.6 km s^{-1}, respectively. The leakage of UV radiation of SFO 62 into the molecular gas might have helped to shape clumps C3, C4, and C5 (e.g., Pomarès et al. 2009).

Clumps C6 and C7 achieve their maximum emission temperature in the velocity range from −25.4 km s^{-1} to −24.9 km s^{-1}. Clump C6, located at (RA, Dec (J2000)) ≈ (11^{h}01^{m}07^s, −59°48′40″), is observed in a small velocity interval (−26.1 km s^{-1} to −25.0 km s^{-1}) and is not morphologically correlated with the nebula. Clump C7, on the other hand, is placed at (RA, Dec (J2000)) ≈ (11^{h}01^{m}10^s, −59°50′30″) and is projected onto the IR nebula close to the location of the MSX compact H II region candidate labeled as source 2 in Paper I

(see Fig. 2). Clump C7 is detected over a velocity interval from −27.1 km s^{-1} to −24.7 km s^{-1}.

In the velocity interval from −25.4 km s^{-1} to −24.9 km s^{-1}, clump C8 becomes noticeable as a patchy structure at (RA, Dec (J2000)) ≈ (11^{h}00^{m}52^s, −59°51′00″), merged to clump C3. It achieves its maximum emission temperature in the velocity range from −24.8 km s^{-1} to −24.3 km s^{-1}. It is barely detected beyond a velocity of ∼−23.7 km s^{-1}. Clump C8 is almost adjacent to SFO 62, which indicates that this clump might be affected by the BRC.

It is worth mentioning that the C^{18}O($J = 2 \rightarrow 1$) line emission, which is a good tracer of high-density molecular gas, is only detected in the velocity range from ∼−26.5 km s^{-1} to −25.1 km s^{-1}, and is mostly concentrated towards the position of clumps C3, C4, and C7 (see Sect. 3.6).

In Fig. 4 (upper panels) we show the ^{13}CO emission distribution integrated in the velocity interval from −17.1 km s^{-1} to −15.3 km s^{-1}. A relatively extended patchy structure is observed at (RA, Dec (J2000)) ≈ (11^{h}01^{m}37^s, −59°50′00″). For the sake of convention, this structure is identified as clump C9. This molecular clump was reported in Paper I as Component 2. From a comparison with the IR emission (right panel) a good correspondence between the external border of C9 and the IR arc can be seen, which suggests a physical association between this clump and the nebula.

From a spectrum obtained in the direction of the MSX CH II region candidate source 1 (from Paper I) we can observe that the bulk of the molecular emission is in the velocity range from ∼19 km s^{-1} to 22 km s^{-1}. In Fig. 4 (lower panels) we show the molecular emission integrated in the velocity range from 18.7 km s^{-1} to 21.7 km s^{-1}. From this figure, a molecular

structure (hereafter clump C10) almost projected over source 1 can be seen. The circular galactic rotation model by Brand & Blitz (1993) locates this clump at 8 kpc. It is probably associated with the larger molecular structure reported in Paper I as Component 3. In the same velocity range another molecular structure (clump C11) is observed at (RA, Dec (J2000)) ≈ ($11^h01^m05^s$, $-59°47'40''$), which is probably associated with clump C10. Since the radio continuum image at 4800 MHz indicates the presence of ionized gas in the direction of C10, additional radio recombination line observations may help to confirm or discard the velocity interval and a physical association between this molecular clump and source 1. Nevertheless, the disparity in the central velocities between C10 and C11 with the rest of the clumps ($\sim$45 km s^{-1}) suggests that these clumps are physically unrelated to NGC 3503. Assuming a distance of $\sim$8 kpc, clumps C10 and C11 turn out to be the most massive clumps in the sample (see Table 3, Sect. 3.2).

In Fig. 5 we show the averaged CO($J = 2 \rightarrow 1$), ^{13}CO($J = 2 \rightarrow 1$), and C^{18}O($J = 2 \rightarrow 1$) spectra obtained inside the emission temperature level which defines each A_{clump}. In Table 2 we present some morphological properties of the clumps and averaged emission line parameters obtained in their direction. Columns (2) and (3) give the coordinates of the center of the clumps. Column (4) lists the area of each clump. In Cols. (5)–(8) the peak emission of the ^{13}CO, C^{18}O, CO, and HCN lines are given. The C^{18}O and HCN peak temperatures are listed only when a value of at least 3 rms noise is achieved. In Col. (9) we list the central velocity obtained by Gaussian fitting of the integrated ^{13}CO spectra within A_{clump}, and Col. (10) indicates the velocity interval of the ^{13}CO line at which each clump is detected.

3.2. Physical properties of the molecular gas

In the previous section we analyzed the morphological and kinematical properties of the molecular gas in the velocity interval from $\sim$−28 km s^{-1} to −24 km s^{-1}, −17.1 km s^{-1} to −15.3 km s^{-1}, and 18.7 km s^{-1} to 21.7 km s^{-1} in the environs of NGC 3503 and SFO 62. Morphological characteristics give evidence of a physical association between the H II region and the BRC with the molecular clumps identified within the velocity interval from $\sim$−28 km s^{-1} to −24 km s^{-1}, and probably from −17.1 km s^{-1} to −15.3 km s^{-1}. In this section, we analyze and compare the physical properties of the molecular clumps aimed at finding some influence of shock fronts or UV radiation on the molecular gas. We include a brief comment on C10 and C11, although, as mentioned before, a physical association of these clumps with NGC 3503 is doubtful.

In Table 3 we list some important physical and dynamical properties derived for the molecular clumps using the averaged spectra from Fig. 5. Column (2) lists the excitation temperature obtained from the CO peak and using Eq. (2). Columns (3) and (4) give the optical depth of ^{13}CO and CO, obtained with Eqs. (3) and (4), respectively. The width of ^{13}CO and CO lines (Δv^{13} and Δv^{12}), defined as the FWHM of the line (see Sect. 2.3.1), is tabulated in Cols. (5) and (6), respectively. The ratio between Δv^{13} and the expected thermal width is listed in Col. (7). The expected thermal width of ^{13}CO is estimated using $\Delta v_{th}^{13} = \sqrt{8 \ln 2\, k\, T_k/m}$, where k is the Boltzman constant, T_k is the kinetic temperature (assumed to be equal to T_{exc}), and m is the mass of the ^{13}CO molecule. The line widths of the CO and ^{13}CO spectra were derived from Gaussian fittings averaging all the spectra within A_{clump}. Columns (8) and (9) give the column

densities at the emission peak and averaged within A_{clump}, respectively. The mass derived assuming LTE and virial equilibrium is listed in Cols. (10) and (11), respectively. There are some uncertainties in measuring M_{LTE} and M_{vir}. In both cases, the values are affected by a distance indetermination of $\sim$15% ($d = 2.9 \pm 0.4$ kpc) which yields uncertainties of $\sim$30% for M_{LTE} ($M_{LTE} \propto d^2$) and $\sim$15% for M_{vir} ($M_{vir} \propto d$). In addition, inaccuracies in the boundary selection ($\sim$20%) can affect the size estimation of the clumps and therefore can produce significant uncertainties in the mass calculations, since a considerable part of the molecular mass might be missed, especially for the cases of clumps C3, C4, C7, and C8 (they have very high emission temperature boundaries above the minimum 5 rms noise). We estimate total uncertainties of about $\sim$50% and $\sim$30% for M_{LTE} and M_{vir}, respectively. It is also worth mentioning that when abundances and isotopologic ratios are considered, accuracy might be within a factor of 2. From Table 3, it can be noted that Δv^{12} is, on average, larger than Δv^{13} by a factor of 1.5. Since the CO molecule is optically thick, some asymmetries in its spectra might be misjudged. For example, clump C1 exhibits a double peak profile in its CO spectrum. This could be a result of self-absorption, which might indicate the existence of hot/warm gas inside the clump. While, the emission of ^{13}CO clearly suggests the existence of a double cloud in the line of sight at different velocities (see Figs. 3 and 5). Then, having the two isotopes provides a way to discern the numbers of components along the line of sight. Similarly, the CO spectra of C5 and C6 show small shoulders. An inspection of their ^{13}CO spectra suggests that these shoulders are the result of a second weaker component at more positive velocities (see also Fig. 3). As a result, the virial masses using Δv^{12} might be overestimated. Therefore, we used Δv^{13} for the calculations. For C1, C5, and C6 we take into account only the strongest molecular components (at more negative velocities).

Molecular clumps that are close to the ionized gas are expected to have different properties than those distant from it, mostly due to shock fronts and stellar FUV radiation impinging onto the cloud. To search for their influence on the molecular gas we analyze the physical properties listed in Table 3.

An analysis of temperatures and densities would be very instructive in this matter. Since T_{exc} is derived using the optically thick CO($J = 2 \rightarrow 1$) emission, it probes the surface conditions of the clouds. An inspection of Table 3 shows that clumps C1, C2, C5, and C6 (from here onwards the cold clumps) achieve temperatures in the range 18−23 K. These values are typical in cold molecular clouds, where cosmic ray ionization is the main heating source. Clumps C3, C4 and C7 (from here onwards the warm clumps) achieve temperatures in the range 39−57 K which suggests that additional local heating sources are present. Clumps C4 and C7 lie at the edge of NGC 3503 and they appear to have been externally heated through the photoionization of their surface layers, as proposed in Paper I. This is reinforced by the presence of a PDR at the interface between the nebula and the clumps (see Fig. 2). For the case of C3, its location (adjacent to SFO 62, see Figs. 1 and 2) would explain its high temperature (39.1 K). It is also worth mentioning that the warm clumps also have higher column densities, which very likely indicates that they are actually formed by gas that has been swept up by the expansion of the ionization and has been condensed. An inspection of Figs. 1 and 2 shows that C4 is trapped between two ionization fronts (NGC 3503 and SFO 62). This means that there might be additional compression, heating and ionization acting upon C4, which might explain the high surface temperature and density derived for this clump. Furthermore, it is the only clump detected
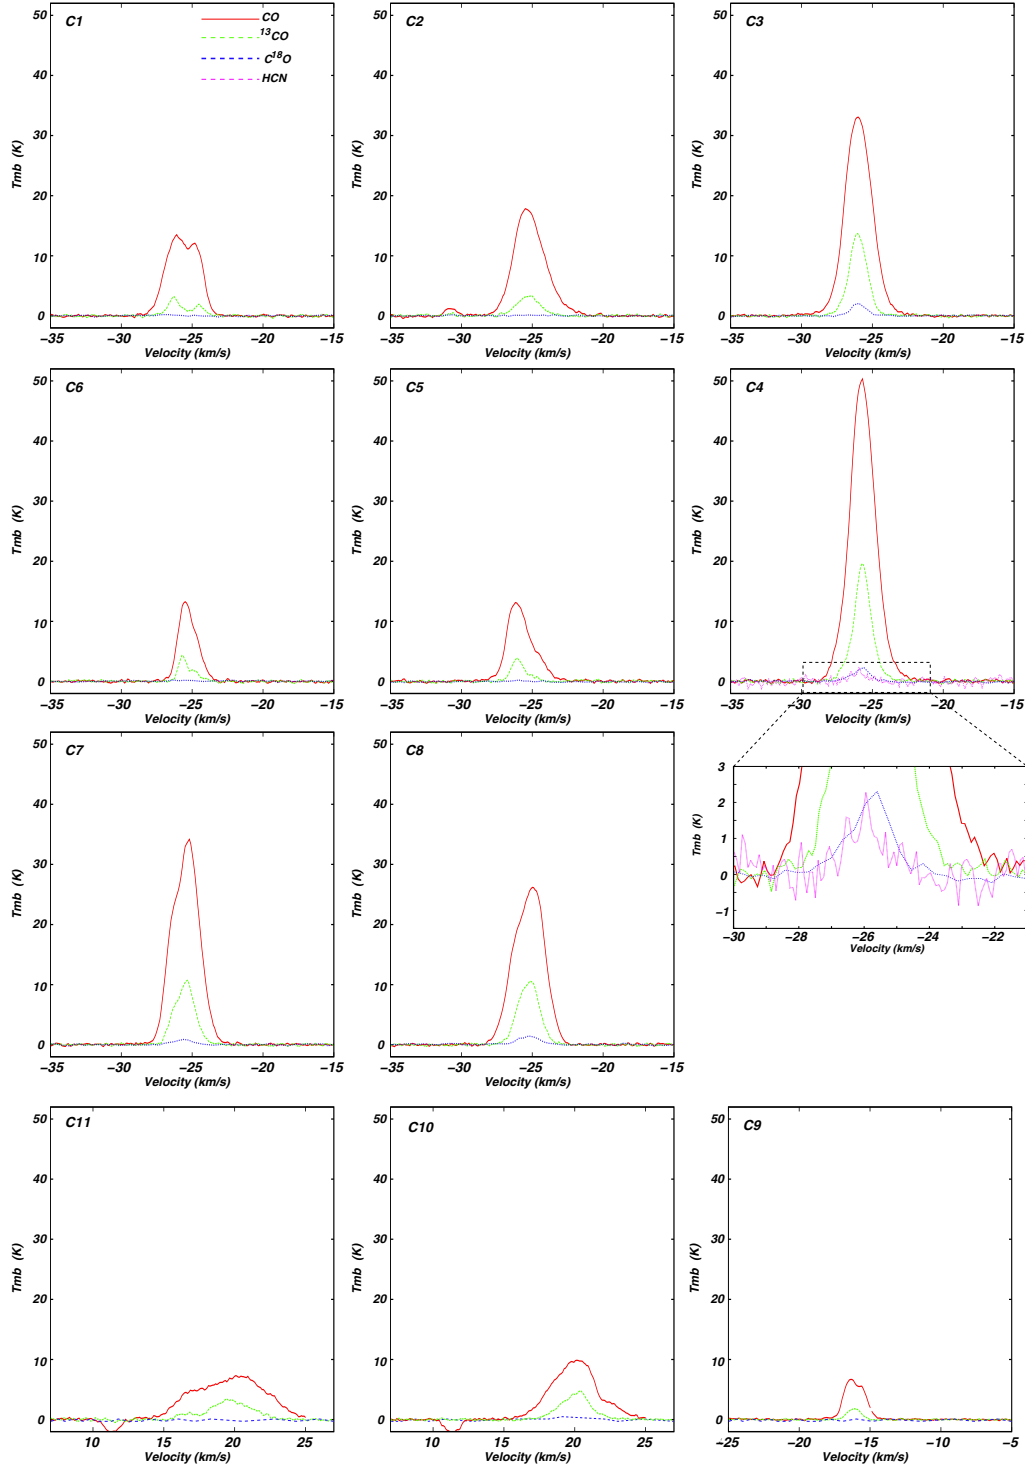

Fig. 5. CO, ^{13}CO, and C^{18}O averaged line spectra obtained towards the molecular clumps C1 to C11. For C4, the spectrum of HCN is shown in the inset.

in HCN emission (see Sect. 3.4). We keep in mind, however, that Pis 17 has probably been formed inside high-density molecular gas close to C4 and C7 that was later evacuated, so an increment in the density of the molecular environment is expected. In addition, star forming processes that are likely occurring inside clumps C3, C4, and probably C7 (see Sect. 3.6) may be contributing to the rise in temperature. Temperature and density of C8 are higher than those of cold clumps, which might implicate external sources of heating and compression. Although

this clump appears to be farther from SFO 62 than C3, an interaction with the ionized gas of the BRC cannot be discarded.

It is also expected that clumps neighboring the Hɪɪ region exhibit signs of turbulence which could be manifested as line widths significantly broadened. However, an inspection of Table 3 shows that all the clumps exhibit line broadenings beyond the natural thermal width. Different from expected, the molecular emission towards clump C2 (which is the most distant from an ionization front), shows the broadest averaged spectra,

Notes. [†] Values obtained adopting a kinematical distance of 8 kpc. Uncertainties were calculated taking into account only innacuracies in the boundary selection.

while clump C4, which clearly shows signs of interactions with the ionization fronts of NGC 3503 and SFO 62 (see the above paragraph), exhibits the lowest ratio between observed and thermal widths. The line width of the averaged spectrum suggests that different parts of the clouds inside A_{clump} have different velocities, rather than showing turbulence effects. Furthermore, the angular resolution of the observations may not be high enough to resolve objects and/or effects in the molecular gas (e.g., outflows, infall, accretion, etc.) that may be contributing to the broadening of the emission line.

Warm clumps have the highest LTE masses (71−282 $M_\odot$), in comparison with colder clumps (7−29 $M_\odot$). This trend is also observed with virialized masses with the exception of C2. An inspection of Table 3 shows that for the case of cold clumps the ratio $M_{\text{LTE}}/M_{\text{vir}}$ is in the range 0.2−0.3. On the other hand, for the case of warm clumps mass ratios $M_{\text{LTE}}/M_{\text{vir}} > 0.6$ were obtained (predominantly >1). Special attention may be required for the case of clump C4, since its M_{LTE} is more than twice as large as M_{vir}. Classical Virial equilibrium analysis establishes that the virial mass is the minimum mass required in order for a cloud to be gravitationally bound. Then, if M_{vir} is larger than M_{LTE} the cloud has too much kinetic energy and is unstable. This seems be the case for cold clumps which are probably expanding as a result of a lack of an external stabilizing pressure. Instead, warm clumps seem to be in virial equilibrium (gravitationally bound) which suggests that the ionization front and UV radiation of the HII region is sufficient to heat up, but not enough to disrupt the molecular gas of the clump.

The presence of two protostellar candidates projected in the direction of C4 (see Sect. 3.6) might indicate that infalling motions may be occurring inside this clump, which is in line with its high $M_{\text{LTE}}/M_{\text{vir}}$ ratio. Nevertheless, new observational results suggest that physical properties of molecular clouds do not agree with the classical interpretation of virial equilibrium (balance between gravitational and kinetic energies) in the sense that an external pressure acting as a confining force is needed (Heyer et al. 2009; Field et al. 2011). We also keep in mind the caveats in the line width determination (see previous paragraph), and hence in determining M_{vir}, which could lead us to mistakenly interpret the results. Higher spatial resolution observations might help to achieve more conclusive results.

We have excluded clumps C9, C10, and C11 from the previous analysis, since it is not clear whether they are physically associated with NGC 3503. As mentioned in Sect. 3.1, the external border of C9 shows a good correspondence with the IR arc. The low density and mass derived for C9 (see Table 3) suggests that this feature might be some residuary molecular gas from the original parental cloud after the HII region has blown into the intercloud medium. The location of C9 (in the opposite side of clumps C4 and C7) and its velocity (shifted by ∼10 km s^{-1}) is in line with this scenario. Clumps C10 and C11 display the largest line widths (and low excitation temperatures), with complex spectra typical of the presence of several velocity components. These characteristics add more support to our previous assumption that clumps C10 and C11 are physically unrelated to the rest of the molecular gas associated with the nebula.
Fig. 7. Mean HCN emission in the velocity range from -26.5 km s^{-1} to -25.5 km s^{-1} (contours) superimposed onto the IRAC-4 image of the nebula (grays). The lowest temperature contour is 0.55 K km s^{-1} ($\sim$5 rms) and the contour spacing temperature is 0.33 K km s^{-1}.

3.3. The velocity field of C4

In the previous section, we analyzed the line width of the averaged clump spectra to look for signposts of a kinematical disturbance produced by the HII region. Different from expected, the averaged spectrum of clump C4 does not seem to be significantly broadened (when compared with the rest of the clumps) by the action of the HII region. However, a careful inspection of Fig. 3 shows that the spatial location of the peak emission of C4 is slightly displaced from RA = $11^h01^m14^s$ to RA = $11^h01^m16^s$ in the velocity range from -27.8 km s^{-1} to -24.9 km s^{-1}, which gives rise to a small velocity gradient. In Fig. 6 we show the position-velocity map along Dec (J2000) = $-59°51'20''$, slicing clumps C3, C4, and C5. Unlike C3 and C5, a noticeable velocity gradient in the peak emission of C4 is detected around the central position of the IR nebula. This velocity gradient can be directly connected to the nebula and could be interpreted as a significant sign of the disturbance in the molecular gas next to the ionization front. According to this interpretation, the expansion of the ionized gas might be affecting the kinematics of the molecular gas adjacent to it (clump C4) giving rise to this kinematical feature. An alternative explanation might be provided from the analysis of the 870 μm emission (see Sect. 3.5). In Figs. 10 and 12 two molecular cores (identified in Sect. 3.5 as D1 and D2) can be noticed in the 870 μm emission ($HPBW = 19''$) inside the ^{13}CO($J = 2 \rightarrow 1$) and C^{18}O($J = 2 \rightarrow 1$) emission of clump C4. Then, C4 might be composed of two different molecular cores at slightly different velocities that are not resolved by carbon monoxide observations ($HPBW = 27''-28''$). These cores can also be noticed in the HCN($J = 3 \rightarrow 2$) emission (see Figs. 7 and 12).

3.4. Denser gas: LVG modeling

In Fig. 5 we have shown that clump C4 has the only detection in the HCN line at a velocity of ~-26 km s^{-1}. In Fig. 7 we show an overlay of the mean HCN emission in the velocity interval from -26.5 km s^{-1} to -25.5 km s^{-1} onto the IRAC-GLIMPSE 4 emission of the nebula. The image shows four small sources placed at RA, Dec (J2000) = ($11^h01^m05^s$, $-59°51'40''$), RA, Dec (J2000) = ($11^h01^m25^s$,

$-59°49'22''$), RA, Dec (J2000) = ($11^h01^m12^s$, $-59°50'40.5''$), and RA, Dec (J2000) = ($11^h01^m14.6^s$, $-59°51'22.7''$). The first three sources are observed in their detection limits ($\sim$5 rms) and will not be considered for further analysis. The fourth source is more extended and achieves a peak temperature of $\sim$2 K at RA, Dec (J2000) = ($11^h01^m16.7^s$, $-59°51'23''$). A second and weaker peak temperature ($\sim$0.8 K) is observed at RA, Dec (J2000) = ($11^h01^m11.6^s$, $-59°51'23.1''$). The spatial location of this source is coincident with the ^{13}CO emission of C4, which clearly suggests that its emission represents the HCN counterpart of that molecular clump. The position of the two emission peaks in the HCN line at RA, Dec (J2000) = ($11^h01^m16.7^s$, $-59°51'23''$) and RA, Dec (J2000) = ($11^h01^m11.6^s$, $-59°51'23.1''$) are almost coincident with the MSX CHII region candidate reported in Paper 1 as source 3 (see Figs. 7 and 12).

Since the HCN molecule has a high critical density, it has been suggested as a ubiquitous high-density molecular gas tracer. Since the spatial resolution of the HCN line is similar to that of the carbon monoxide lines, their emission can be used to obtain a robust estimation of the volume density using the large velocity gradient (LVG) formalism (Scoville & Solomon 1973; Goldreich & Kwan 1974) for radiative transfer of molecular emission lines. We performed the LVG analysis with the code written by L. G. Mundy and implemented as part of the MIRIAD[7] package of SMA. For a given kinetic temperature (T_k), this program estimates the line radiation temperature of a molecular transition as a function of the molecular column density (normalized by the line width) and H$_2$ volume density. Considering that $T_k \approx T_{exc}$ at densities higher than 10^4 cm^{-3} (Hayakawa et al. 1999), and that $T_{exc} = 57.2$ K (see Table 3), we adopted kinetic temperatures in the range 50 K $\leq T_k \leq$ 80 K which are also typical temperatures derived for molecular clouds close to OB associations (Ohama et al. 2010). Nevertheless, we also find that the derived densities are relatively insensitive to T_k in this range. We use the ^{13}CO molecule adopting a canonical abundance [^{13}CO]/[H$_2$] = 2×10^{-6} (Dickman 1978). For the case of HCN, its abundance is less certain making it the main source of error. We adopted the abundance range derived for Orion-KL ([HCN]/[H$_2$] = 2×10^{-8}–2×10^{-9}; Schilke et al. 1992).

[7] http://www.cfa.harvard.edu/sma/miriad/packages/

Fig. 8. LVG models for ^{13}CO and HCN peak temperatures as a function of normalized column density and volume density. We adopted abundances $[^{13}$CO$]/[H_2] = 2 \times 10^{-6}$ and $[HCN]/[H_2] = (2-20) \times 10^{-8}$. The green lines trace the contours of ^{13}CO peak intensity, while the red lines trace the contours of HCN peak intensity. Dotted black lines are where solutions are coincident.

In Fig. 8 we show the 50×50 model grids of ^{13}CO($J = 2 \to 1$), and HCN($J = 3 \to 2$) over a volume density range $n(H_2) = 10^3 - 10^8$ cm^{-3}. For the ^{13}CO($J = 2 \to 1$) line, the normalized column density ranges are N^{13}(CO)/$\Delta v = 10^{13} - 10^{18}$ cm^{-2} (km s^{-1})$^{-1}$. At these high densities, the ^{13}CO line is in collisional equilibrium and is almost independent of $n(H_2)$. The HCN, however, has higher critical density and its line strength can be used to diagnose $n(H_2)$ in this range. The dotted line in each panel of Fig. 8 shows the range of values where the solutions for both molecular species coincide, indicating that volume density in clump C4 is in the range from 4×10^4 to 5.6×10^5 cm^{-3}. These values are higher than that obtained from the LTE assumption ($n(H_2)_{LTE} \sim 1 \times 10^4$ cm^{-3}), although this value is highly dependant on distance and geometry (assumed to be spherical) and a comparison might not be conclusive. In the LVG analysis we have used HCN abundances obtained in Orion-KL, although lower abundances were derived for a number of galactic molecular clouds (e.g. 0.6×10^{-10}, Johnstone et al. 2003; 7×10^{-10}, Tennekes et al. 2006) which would highly shift the HCN lines up relative to ^{13}CO, implying higher densities ($>10^6$ cm^{-3}). It is well accepted that volume densities higher than 10^5 cm^{-3} are critical for the initial condition of stellar formation (Elmegreen 2002). Furthermore, two candidate YSOs were identified close to the HCN emission peak and projected onto the center of C4 (see Fig. 12 in Sect. 3.6) which suggests that the star formation process may be occurring inside this dense clump. In order to obtain the ^{13}CO column density, we multiplied the inferred value of N^{13}(CO)/Δv by the line width, which yields N^{13}(CO) $\sim 2.4 \times 10^{16}$ cm^{-2}.

3.5. Continuum dust emission

Optically thin submillimeter continuum emission at 870 μm is usually dominated by the thermal emission from cold dust, which is contained in dense material (e.g., dense molecular cores or filaments).

In the upper panel of Fig. 9 we display the image at 870 μm extracted from ATLASGAL. The image shows an extended source centered at RA, Dec (J2000) = (11^{h}01^{m}11^s, $-59°51'$). The brightest section of the source extends along Dec (J2000) = $-59°51'36''$, from RA = 11^{h}01^{m}01^s to 11^{h}01^{m}22^s. Three clumps can be easily identified; the brightest one to the east, and the faintest one to the west. Their positions are RA, Dec (J2000) = (11^{h}01^{m}17.4^s, $-59°51'36''$), RA, Dec (J2000) = (11^{h}01^{m}12.6^s, $-59°51'36''$), and RA, Dec (J2000) = (11^{h}01^{m}05.2^s, $-59°51'36''$), indicated in the upper panel of Fig. 9 as D1, D2, and D3, respectively. A fainter clump, named D4, is placed at RA, Dec (J2000) = (11^{h}01^{m}08.7^s, $-59°50'30''$). The four dust clumps are immersed in a faint plateau of emission.

A comparison of the image at 870 μm and the ^{13}CO images in Fig. 3 shows that D1 and D2 are the dust counterparts of C4, while D3 partially coincides with C3, and D4 with C7. We also note that the region of low molecular emission present at RA, Dec (J2000) = (11^{h}01^{m}06.3^s, $-59°50'55''$), between C3 and C7, does not show emission at 870 μm. Clearly, the dust emission is the counterpart of the molecular emission. Clumps D1 and D2 are also detected in the HCN line (see Fig.12 in Sect. 3.6).

Table 4. Parameters of the dust clumps detected at 870 μm.

Dust clump	RA (^{h} ^{m} ^{s})	Dec (J2000) ($^\circ$ $'$ $''$)	$R_{\rm eff}$ (arcsec)	S_{870} (Jy)	$M_{\rm dust}(20\,{\rm K})^\ddagger$ ($M_\odot$)	$M_{\rm dust}(30\,{\rm K})^\ddagger$ ($M_\odot$)	$M_{\rm dust}(40\,{\rm K})^\ddagger$ ($M_\odot$)	^{13}CO counterpart

Notes. $^{(\dagger)}$ Values obtained adopting a distance of ∼8 kpc. $^{(\ddagger)}$ Dust mass derived from the continuum emission at 870 μm.

**Fig. 9.** *Upper panel*: 870 μm continuum emission map from ATLASGAL. The grayscale goes from 50 mJy beam^{-1} to 500 mJy beam^{-1}. Contour levels correspond to 150 (∼2.5 rms), 300, 500, and 700 mJy beam^{-1}. *Bottom panel*: overlay of IRAC image at 8 μm and the coutour levels of the *upper panel*. The grayscale goes from 10 MJy ster^{-1} to 180 MJy ster^{-1}.

Two additional patches of emission are detected at 870 μm: one at RA, Dec (J2000) = (11^{h}01^{m}13.5^s, −59°49′00″) (D5) and the other at RA, Dec (J2000) = (11^{h}01^{m}05.5^s, −59°47′48″) (D6). Clumps D5 and D6 seem to be the dust counterparts of the molecular clumps C10 and C11, detected in the velocity interval from +18.7 km s^{-1} to +21.7 km s^{-1} (see Fig. 3). In particular, D5 coincides with a faint source detected in the radio continuum at 4800 MHz and a bright source at 8 μm (see Fig. 2). The 2MASS candidate YSOs 1 and 12 from Paper I coincide with this region, suggesting that this is a candidate star forming region. Surprisingly, the emissions at both 870 μm and ^{13}CO extend slightly to the northwest, opposite the position of the central cavity of NGC 3503 and the exciting stars, suggesting a relation to these object. However, as mentioned in Sect. 3.1, for

a velocity of ∼+20 km s^{-1} the circular galactic rotation model predicts distances of about 8 kpc, far away from NGC 3503. For D6, it displays an arc-shaped morphology encircling a point-like source detected at 4.5 μm and 8 μm (labeled in Sect. 3.6 as 2MASS candidate YSO 22 and WISE candidate YSO 65).

Table 4 lists flux densities and masses of the dust clumps. Dust mass estimates ($M_{\rm dust}$) were obtained using Eq. (9) considering a conservative dust temperature range between 20 K and 40 K. Values in the range 20−30 K are assumed for cold clumps and protostellar condensations (Johnstone et al. 2006; Deharveng et al. 2009), while the last value was derived from the emissions at 60 μm and 100 μm (see Paper I). For dust clumps D5 and D6 we have adopted a distance of 8 kpc, in common with molecular clumps C10 and C11, although a physical association with NGC 3503 cannot be discarded without having information on the velocity of the ionized gas of MSX source 1.

3.6. A new identification of candidate YSOs

As pointed out in Sect. 1, a search for candidate YSOs in the environs of NGC 3503 was performed in Paper I using the IRAS, MSX, and 2MASS point source catalogs. To accomplish a more complete study, we have extended the search to a larger area around the nebula and we have included new data. We intend to study the star formation in the vicinity of NGC 3503 by detecting all the candidate YSOs (intrinsically reddened) and analyzing their position with respect to the dust, ionized gas, and molecular gas.

In this new analysis we have again used the 2MASS catalog (Cutri et al. 2003), which provides detections in the J, H, and K_s bands, to search for point sources with infrared excess. We have selected only sources with signal-to-noise ratio (S/N) > 10 (quality AAA) and followed the criteria of Comerón et al. (2005), to determine the parameter $q = (J - H) - 1.83 \times (H - K_s)$. Then, sources with $q < -0.15$ (i.e., sources with IR excess) were identified as candidate YSOs. In Table 5 we have listed the 2MASS candidate YSOs identified with the method explained above. For completeness, we have also included in the table the three MSX CHII region candidates reported in Paper I. For the sake of clarity, the numerical identification up to source 12 is compatible with that of Paper I. The spatial distribution of 2MASS and MSX sources is depicted in Fig. 10. As can be seen from this figure, from a total of 61 sources detected in the field, only 10 sources are projected onto the IR counterpart of NGC 3503 or its central cavity, namely 4, 5, 6, 7, 8, 9, 11, 12, and 22 (for completeness, in Fig. 10 we have included all the 2MASS candidate YSOs detected in the studied area). Sources 4 to 12 were previously reported in Paper I as possibly associated with the nebula. Sources 4−7 are projected towards the central cavity of NGC 3503, and
Fig. 10. Composite image of NGC 3503 and its environs. The red color shows the IRAC-GLIMPSE emission at 8.0 μm, while green/yellow tonalities show the ATLASGAL 870 μm continuum emission. The ^{13}CO($J = 2 \rightarrow 1$) emission line integrated in the velocity ranges from -27.8 km s^{-1} to -23.7 km s^{-1} and -17.1 km s^{-1} to -15.3 km s^{-1} are shown in blue contours. Thick light blue circles indicate the position of the MSX CHII region candidates, while yellow crosses depict the position of the 2MASS sources with IR excess. Green and white diamonds indicate the position of WISE Class I and Class II candidate YSOs, respectively. Numerical references of YSOs are based on Tables 5 and 6. The size of the symbols do not match the angular size of the sources.

lie inside the radio continuum counterpart of the nebula (see Fig. 2) while sources 8, 9, and 11 lie on the IR arc towards the eastern and northern sections of IR the nebula. Low-intensity radio continuum emission is also seen projected onto these sources (see Fig. 2). Source 22 is coincident with a point-like source detected in the four IRAC bands, and correlates with the emission at 870 μm of D6 (see Figs. 9 and 10) and clump C11, suggesting that this candidate YSO is buried in a cocoon of cold dust and dense gas. Its WISE counterpart can be classified as a Class I candidate (source 65; see below). None of the above mentioned 2MASS sources are seen projected onto the molecular gas associated with the nebula at velocities between -27.8 km s^{-1} and -23.7 km s^{-1} or -17.1 km s^{-1} and -15.3 km s^{-1} (see Fig. 10); 2MASS sources (15, 16, 29, 34, 38, 40, 45, and 50) appear projected onto the northwestern and western borders of the molecular gas in the velocity range from -27.8 km s^{-1} to -23.7 km s^{-1} far from the nebula, thus, a physical association with the molecular environment of NGC 3503 is uncertain. Source 32 is projected onto the molecular component at velocities between -17.1 km s^{-1} and -15.3 km s^{-1} (clump C9).

Candidate YSOs are usually classified, according to their evolutionary phase, into two standard categories: 1) Class I YSOs which are young protostellar sources embedded in dense infalling envelopes of gas and dust; and 2) Class II YSOs which are pre-main-sequence sources whose emission originates

mainly in dense optically thick disks around the protostar (candidate T Tauri stars). These sources exhibit an infrared excess that cannot be attributed to the ISM along the line of sight, but rather to the envelope and/or the disk surrounding the protostar. Class III sources are usually referred to as pre-main-sequence (or main-sequence) field stars. With the aim of identifying new candidate YSOs associated with NGC 3503, we have included in our analysis photometric data of WISE (Wright et al. 2010) obtained from the IPAC database[8]. This survey maps the whole sky in four bands centered at 3.4, 4.6, 12, and 22 μm. We have used the criteria of Koenig et al. (2012), biased against the youngest and least massive candidate YSOs, as follows: after removing contamination arising from background objects like galaxies (very red in [4.6] $-$ [12]), broad-line active galactic nuclei (of similar colors to YSOs, but distinctly fainter) and resolved PAH emission regions (redder than the majority of YSOs), we identified infrared excess sources demanding that

$$[3.4] - [4.6] - \sigma_1 \quad > 0.25$$
$$[4.6] - [12.0] - \sigma_2 > 1.0,$$

where [3.4], [4.6], and [12.0] are the WISE bands 1, 2, and 3 mag, respectively, and $\sigma_1 = \sigma([3.4] - [4.6])$ and $\sigma_2 = \sigma([4.6] - [12.0])$ indicate the combined errors of [3.4] $-$ [4.6]
---

[8] http://irsa.ipac.caltech.edu/cgi-bin/Gator/nph-dd

and [4.6] − [12.0] colors, added in quadrature. Class I sources are a subsample of this defined by

$$[3.4] − [4.6] > 1.0$$
$$[4.6] − [12.0] > 2.0,$$

the rest are Class II objects. For the method explained above, we have considered sources with errors in magnitude lower than 0.2 mag in bands 1−3.

In Table 6 we list the candidate YSOs identified with the method explained above. For the sake of clarity, the numerical identification follows that of Table 5. We found a total of 36 sources (12 Class I and 24 Class II candidates). In Fig.11 we show the WISE band 1, 2, and 3 color−color diagram depicting the distribution of sources listed in Table 6. The spatial location of Class I and Class II candidates is illustrated in Fig. 10. Unlike 2MASS sources, the spatial distribution of WISE sources is concentrated toward the nebula. Sources 67, 68, 74, 75 (which is co-incident with 2MASS source 6), 78, 80, 88, and 91 are projected toward the center of the nebula and its radio continuum emission (see Fig. 2), while sources 66, 77, 81, 83, 90, and 94 are seen projected onto the IR arc. Sources 72 and 73 are almost coincident with the MSX CHII region candidate 1 and 2MASS candidate YSO 12. Source 70 is projected close to the peak of emission of the molecular component at velocities between -17.1 km s^{-1} and -15.3 km s^{-1} (clump C9).

None of the WISE candidate YSOs sources mentioned so far have been observed in the direction of any molecular clump detected in the velocity range from -27.8 km s^{-1} to -23.7 km s^{-1}. Instead, three protostellar sources, 71, 76, and 85, have been observed in the direction of the ^{13}CO emission peaks corresponding to clumps C4 and C3, which are the densest clumps (see Sect. 3.2). In order to better trace the spatial distribution of the gas/dust and candidate YSOs in this region, in Fig. 12 we present a composite image of HCN, C^{18}O, and 870 μm emission, superimposed on the location of WISE sources 71, 76, and 85. Sources 71 and 85 are projected onto dust clumps D2 and D1, respectively, and outwardly a C^{18}O peak emission of seen at RA, Dec (J2000) = (11^{h}01^{m}15^s, $-59°51'20''$) (C^{18}O counterpart of clump C4). Source 85 is almost projected onto the HCN peak at RA, Dec (J2000) = (11^{h}01^{m}16.7^s, $-59°51'23''$), while the position of source 71 is close to the HCN peak seen at RA, Dec (J2000) = (11^{h}01^{m}11.6^s,

Fig. 12. Composite image showing the emission of the HCN($J = 3 \rightarrow 2$) line (green contours), the C^{18}O($J = 2 \rightarrow 1$) line (white/black contours), and the 870 μm continuum emission (grayscale) in the central region of NGC 3503. The velocity ranges are -26.2 km s^{-1} to -25.2 km s^{-1} and -26.5 km s^{-1} to -25.5 km s^{-1} for the C^{18}O and HCN lines, respectively. Red triangles depict the position of WISE candidate YSOs 71, 76, and 85. The C^{18}O counterparts of clumps C3, C4, and C7 are indicated. The beam sizes are shown in the lower-left corner.

$-59°51'23.1''$) and the central position of the MSX CHII region candidate source 3. This very likely suggests that these sources were formed inside high-density molecular cores. Source 76 is seen projected close to the direction of a C^{18}O peak seen at RA, Dec (J2000) = (11^{h}01^{m}2.5^s, $-59°50'15''$) (very likely the C^{18}O counterpart of clump C3) and coincident with the dust clump D3 seen at 870 μm. This protostellar source is also projected onto the weaker HCN structure located at RA, Dec (J2000) = (11^{h}01^{m}05^s, $-59°51'40''$). As suggested in Sect. 3.2, clump C4 is probably exposed to extra compression, heating, and ionization from NGC 3503 and SFO 62, which might have triggered/enhanced the formation of protostellar candidates 71 and 85 (and probably 76) in the densest regions of the molecular gas. It is also worth highlighting the location of WISE sources 69, 82, 89, 93, 95, 96, and 98, which are spatially aligned following the eastern border of molecular clumps C4, C6, and C7. The location of these protostellar sources suggests that they are linked to the collected layers of molecular gas because of the expansion of the ionization front of NGC 3503 over its molecular environment, which has probably aided the stellar formation activity along the external borders of the molecular gas.

To determine whether the fragmentation of the collected layer via the collect-and-collapse process might have triggered the star formation in the environs of NGC 3503, in Paper I we made use of the analytical model of Whitworth et al. (1994) for expanding HII regions. We obtained that $t_{frag} \sim 3.5 \times 10^6$ yr and $R_{frag} \sim 7.5$ pc, which are considerably larger than the age (t_{dyn}) and size (R_{HII}) of NGC 3503 (derived assuming a classical expanding HII region; Dyson & Williams 1997). This lead us to conclude that fragmentation of the collected layer triggered by the expansion of the nebula is doubtful. We keep in mind, however, that newer simulations have shown that accretion and ionization may occur simultaneously for compact HII regions, which makes their size unrelated to their age until late in their lifetimes (Peters et al. 2010).

Given the lack of certainty of this scenario, we have considered alternative approaches: the formation of YSOs lying at the border of the HII region (sources 69, 82, 89, 93, 95, 96, and 98) and inside clumps C4 and C3 (sources 71, 76, and 85) probably results from an interaction of the ionization front of NGC 3503 (and SFO 62) with pre-existing gravitationally bound molecular condensations (C3, C4, and C7; see Sect. 3.2), which has enhanced the formation of the protostellar objects (RDI process; Lefloch & Lazareff 1994). In addition, the formation of the protostellar candidates may be the result of small-scale Jeans gravitational instabilities in the collected layers of molecular gas (e.g., Pomarès et al. 2009; Paron et al. 2011). Higher spatial resolution molecular observations might help to shed some light on these issues.

4. Summary

Using APEX CO($J = 2 \rightarrow 1$), ^{13}CO($J = 2 \rightarrow 1$), C^{18}O($J = 2 \rightarrow 1$), and HCN($J = 3 \rightarrow 2$) line data, and ATLASGAL 870 μm images, we carried out a multifrequency study of the molecular gas and dust associated with the HII region/star forming region NGC 3503. To analyze the star formation process in the region we made use of the WISE and 2MASS data obtained from the IPAC archive. This work is a follow-up study of Duronea et al. (2012). The main results can be summarized as follows:

1. The ionized gas of NGC 3503 is expanding against the molecular gas component in the velocity range from ~ -28 km s^{-1} to -23 km s^{-1}. The morphology of the molecular gas close to the nebula, the location of the PDR, and the shape of radio continuum emission confirm the champagne flow scenario proposed in Paper I.

2. New APEX observations allowed the small scale structure of the molecular gas associated with the nebula (previously reported in Paper I) to be fully imaged. We identified several molecular clumps (C1 to C11) and studied their physical and dynamical properties to investigate the impact of the expanding nebula and/or the southern bright rimmed cloud SFO 62 onto the molecular gas.

3. We found that warmer clumps (C3, C4, and C7) are close to the HII region, which is indicative of an external heating source, most probably photoionization of their surface molecular layers by the intense UV field of Pis 17. Warmer clumps are also denser, which suggests that they are submitted to an external compression due to the expansion of NGC 3503. These clumps are very likely molecular gas of the parental cloud that has been swept up by the expansion of the ionization front and has been condensed. Clump C4 is also adjacent to SFO 62, which might explain its very high temperature and density. A noticeable velocity gradient is detected in C4. This gradient may be indicative of a kinematical disturbance, or else be the consequence of two molecular cores at slightly different velocity that are not fully resolved in the carbon monoxide emissions.

4. Clumps located near NGC 3503 also have the highest LTE and virialized masses. They also exhibit the highest $M_{\mathrm{LTE}}/M_{\mathrm{vir}}$ ratio (predominantly >1), which, according to the classical interpretation, indicates that they are gravitationally bound.

5. All molecular clumps exhibit line broadening beyond the thermal width, which possibly indicates that in some cases the line widths of the composite spectrum of the clumps have different velocities, rather than showing turbulence effects.

Also, spatially unresolved process like ouflows, infall, accretion, etc., might be contributing to the broadening.

6. We have analyzed the 870 μm emission, characteristic of filaments and dense molecular cores. We detected emission only in the direction of clumps C3, C4, and C7. This is also indicative of high-density gas.

7. We have presented some evidence of stellar formation in the region by detecting sources with IR excess. Unlike 2MASS candidate YSOs, WISE Class I and Class II candidates show a spatial distribution concentrated to the IR nebula. Several sources are detected along the external border of two of the densest molecular clumps (C4 and C7) which suggests that they might be formed in the compressed layers of molecular gas. Three sources are projected close to HCN, C^{18}O, and 870 μm emission peaks (coincident with the position of clumps C4 and C3). This very likely indicates that they were born inside high-density molecular cores, making clumps C4 and C3 excellent candidates with which to further investigate star formation with higher spatial resolution instruments like ALMA.

8. Since the dynamical age and fragmentation time derived for the molecular layer differ from the age and radius of the nebula (Paper I) we have excluded the collect-and-collapse scenario for the YSO formation. Instead, we have proposed here some alternative mechanisms, such as radiative-driven implosion in pre-existing gravitationally bound clumps (C3, C4, and C7), or small-scale Jeans gravitational instabilities in the swept-up layers of molecular gas.
