#### Abstract

The study of the planet-debris disk connection can shed light on the formation and evolution of planetary systems and may help "predict" the presence of planets around stars with certain disk characteristics. In preliminary analyses of subsamples of the Herschel DEBRIS and DUNES surveys, Wyatt et al. and Marshall et al. identified a tentative correlation between debris and the presence of low-mass planets. Here we use the cleanest possible sample out of these Herschel surveys to assess the presence of such a correlation, discarding stars without known ages, with ages $<1 \mathrm{Gyr}$, and with binary companions $<100 \mathrm{AU}$ to rule out possible correlations due to effects other than planet presence. In our resulting subsample of 204 FGK stars, we do not find evidence that debris disks are more common or more dusty around stars harboring high-mass or low-mass planets compared to a control sample without identified planets. There is no evidence either that the characteristic dust temperature of the debris disks around planet-bearing stars is any different from that in debris disks without identified planets, nor that debris disks are more or less common (or more or less dusty) around stars harboring multiple planets compared to singleplanet systems. Diverse dynamical histories may account for the lack of correlations. The data show a correlation between the presence of high-mass planets and stellar metallicity, but no correlation between the presence of lowmass planets or debris and stellar metallicity. Comparing the observed cumulative distribution of fractional luminosity to those expected from a Gaussian distribution in logarithmic scale, we find that a distribution centered on the solar system's value fits the data well, while one centered at 10 times this value can be rejected. This is of interest in the context of future terrestrial planet detection and characterization because it indicates that there are good prospects for finding a large number of debris disk systems (i.e., with evidence of harboring planetesimals, the building blocks of planets) with exozodiacal emission low enough to be appropriate targets for an ATLASTtype mission to search for biosignatures.

Key words: circumstellar matter - infrared: stars - interplanetary medium - Kuiper Belt: general - planet-disk interactions - planetary systems

## 1. INTRODUCTION

Planetesimals are the building blocks of planets, and midand far-infrared observations with Spitzer and Herschel indicate that at least $10-25 \%$ of mature stars (ages of 10 Myr to 10 Gyr ) with a wide range of masses (corresponding to spectral types $\mathrm{A}-\mathrm{M}$ ) harbor planetesimal disks with disk sizes of tens to hundreds AU. This frequency is a lower limit because the surveys are limited by sensitivity. The evidence for planetesimals comes from the presence of
infrared emission in excess of that expected from the stellar photosphere, thought to arise from a circumstellar dust disk; because the lifetime of the dust grains $(<1 \mathrm{Myr})$ is much shorter than the age of the star ( $>10 \mathrm{Myr}$ ), it is inferred that the dust cannot be primordial but must be the result of steady or stochastic dust production generated by the collision, disruption, and/or sublimation of planetesimals (for reviews, see Wyatt 2008; Krivov 2010 ; Moro-Martín 2013; Matthews et al. 2014).

The Sun harbors such a debris disk, produced by the asteroids, comets, and Kuiper Belt objects (Jewitt et al. 2009) with a dust production rate that has changed significantly with time, being higher in the past when the asteroid and Kuiper belts (KBs) were more densely populated (Booth et al. 2009). Today, the solar system's debris disk is fainter than the faintest extrasolar debris disks we can observe with Herschel (Moro-Martín 2003; Vitense et al. 2012), with a $3 \sigma$ detection limit at 10-20 times the level of dust in the current KB (Eiroa et al. 2013; B. C. Matthews et al. 2015, in preparation). There is evidence of planetesimals around A- to M-type stars in both single- and multiple-star systems. These stars span several orders of magnitude difference in stellar luminosities, implying that planetesimal formation, a critical step in planet formation, is a robust process that can take place under a wide range of conditions.
It is therefore not surprising that planets and debris disks coexist (Beichman et al. 2005; Moro-Martín et al. 2007b, 2010; Maldonado et al. 2012; Wyatt et al. 2012; Marshall et al. 2014). However, based on Spitzer debris disk surveys, no statistical correlation has been found to date between the presence of known high-mass planets and debris disks (MoroMartín et al. 2007a; Bryden et al. 2009; Kóspál et al. 2009). These studies were focused on high-mass planets $\left(>30 M_{\oplus}\right)$ because, at the time, the population of low-mass planets was unknown. Overall, the lack of correlation was understood within the context that the conditions to form debris disks are more easily met than the conditions to form high-mass planets, in which case one would not expect a correlation based on formation conditions; this was also consistent with the studies that showed that there is a correlation between stellar metallicity and the presence of massive planets (Santos et al. 2004; Fisher \& Valenti 2005; Maldonado et al. 2012), but there is no correlation between stellar metallicity and the presence of debris disks (Bryden et al. 2006; Greaves et al. 2006; Maldonado et al. 2012).

Recent results from the radial velocity surveys indicate that, similar to debris disks, there is no correlation between the presence of low-mass planets and stellar metallicity (Ghezzi et al. 2010; Mayor et al. 2011; Buchhave et al. 2012). This might indicate that the conditions to form low-mass planets are more easily met than those to form high-mass planets. A natural question to ask is whether low-mass planets and debris disks are correlated.

A correlation between terrestrial planets in the inner region of the planetary systems and cold debris dust has been predicted to exist based on a comprehensive set of dynamical simulations consisting of high-mass planets, embryos, and inner and outer belts of planetesimals. These simulations find a strong correlation between the presence of cold dust and the occurrence of terrestrial planets because systems with cold dust imply a calm dynamical evolution where the building blocks of low-mass planets have been able to grow and survive; on the other hand, systems with dynamically active high-mass planets tend to destroy both the outer dust-producing planetesimal belt and the building blocks of the terrestrial planets (Raymond et al. 2011, 2012).
Herschel observations have opened a new parameter space that allows us to explore fainter and colder debris disks, improving our knowledge of debris disk frequency, in particular around later-type stars. In addition, since the Spitzer planet-debris disk correlation studies were carried out, a large
number of low-mass planets have been detected, the frequency of which can now be characterized. Tentative detection of a correlation between low-mass planets and debris disks was presented in Wyatt et al. (2012) from a preliminary study based on a Herschel-DEBRIS subsample of the nearest 60 Gtype stars, which was also seen in the volume-limited sample of radial velocity planet host stars examined by Marshall et al. (2014). In this paper, we revisit the planet-debris disk correlation (or lack thereof) in the Herschel DEBRIS and DUNES surveys (Eiroa et al. 2010;2013; Matthews et al. 2010; B. C. Matthews et al. 2015, in preparation) to assess whether the frequency and properties of debris disks around a control sample of stars are statistically different from those around stars with high-mass or low-mass planets. In a companion paper (Marshall et al. 2014), we describe the individual exoplanet host systems, their debris disks, and the disk dependencies on planetary system properties such as planet semimajor axis and eccentricity.
The selection criteria of the different samples used in this study are presented in Section 2 (with a discussion of biases in Section 5). A detailed discussion of the statistical analysis using Kolmogorov-Smirnov (K-S), Fisher's exact, and survival analysis tests can be found in Section 3 (regarding the frequency and properties of debris disks and their dependence on the presence of high-mass and low-mass planets), Section 4 (regarding the correlation with stellar metallicity), and Section 6 (regarding the distribution of the debris disk fractional luminosities). For a summary and discussion of our results the reader is directed to Section 7.

## 2. SAMPLE SELECTION

Table 1 lists the selection criteria of the different samples of stars used in our statistical analysis. Table 2 gives information on their stellar parameters, and Table 3 lists the observed fluxes and photospheric estimates at $100 \mu \mathrm{~m}$ and the strength of the excess emission. Detailed information on the procedures followed in this paper for source extraction, photosphere subtraction, and SED fitting can be found in Kennedy et al. (2012a, 2012b).

All the stars included in this study are drawn from the Herschel DEBRIS and DUNES surveys. DEBRIS is an unbiased volume-limited survey for M-, K-, G-, F-, and Atype stars, where the volume limits are $8.6,15.6,21.3,23.6$, and 45.5 pc , respectively (Phillips et al. 2010; Matthews 2010; B. C. Matthews et al. 2015, in preparation). The DUNES survey covers mid-F- to mid-K-type stars within 20 pc (irrespective of planet or debris disk presence), plus a handful of stars within 25 pc known to harbor planets and/or debris disks (Eiroa et al. 2010, 2013).

### 2.1. Set 1: Control Sample Irrespective of Planet and Debris Disk Presence

To maximize completeness from the DEBRIS and DUNES surveys, we selected for Set 1 all the FGK stars within 20 pc.
The Spitzer surveys found that the upper envelope of the $70 \mu \mathrm{~m}$ debris disk emission shows a decline over the $\sim 100 \mathrm{Myr}$ of a star's lifetime (Bryden et al. 2006; Hillenbrand et al. 2008; Carpenter 2009). Therefore, to avoid introducing biases due to stellar age, we further restrict the control sample to stars with ages $>100 \mathrm{Myr}$ (of the stars with known ages, only three were excluded because of youth). Our stellar ages are obtained from

Table 1
Sample Description

| Set | Description |
| :---: | :---: |
| 1 | FGK stars in DEBRIS and DUNES with distances $<20 \mathrm{pc}$, ages $>100 \mathrm{Myr}$, and no binary companions at $<100$ AU |
| 2 | Subset from Set 1 without known planets |
| 3 | Subset from Set 1 harboring high-mass planets with masses $>30 M_{\oplus}$ |
|  | 3a: for planets at $>0.1 \mathrm{AU}$ <br> 3 b : for planets at 0.1 AU |
| 4 | Subset from Set 1 harboring low-mass planets with masses $<30 M_{\oplus}$ |
| 5 | Subset from Set 1 harboring excess emission at $100 \mu \mathrm{~m}$, i.e., with $\left.\left(F_{100}-F_{*, 100}\right) / \sigma_{100}>3\right)$ |
| 6 | Subset from Set 1 with single planets |
| 7 | Subset from Setl with multiple planets |
| 1y, 2y, 3ay, 3by, 4y, 5y | Subsets from Sets $1-5$ with ages $<1$ Gyr |
| 1o, 2o, 3ao, 3bo, 4o, 5o | Subsets from Sets $1-5$ with ages $>1 \mathrm{Gyr}$ |
| 1oy, 2oy | Subsets from Sets 1 and 2 with ages 0.1-5 Gyr |
| 100, 200 | Subsets from Sets 1 and 2 with ages $>5 \mathrm{Gyr}$ |
| 11, 2l, 3al, 3bl, 41, 51 | Subsets from Sets $1-5$ with metallicities smaller than the average $[\mathrm{Fe} / \mathrm{H}] \leqslant-0.12$ |
| 1h, 2h, 3ah, 3bh, 4h, 5h | Subsets from Sets $1-5$ with metallicities larger than the average $[\mathrm{Fe} / \mathrm{H}]>-0.12$ |
| 1t, 2t, 3at, 3bt, 4t, 5t | Subsets from Sets 1-5 with estimated dust temperature, assuming a blackbody |

Vican et al. (2012) and Eiroa et al. (2013). Stellar ages can be very uncertain, and individual systems may end up in the wrong age bin. ${ }^{22}$ However, for a statistical analysis such as the one in this paper, the best approach is to use an age database as "uniform" as possible. Our ages are based on gyrochronology, Ca if chromospheric emission ( $\mathrm{R}^{\prime}{ }_{\mathrm{HK}}$ ), and X-ray flux, always in that order of priority, acknowledging the decreasing reliability of the corresponding age measurements. Gyrochronology ages come from Vican et al. (2012) and are available for 17 stars in our sample; they can be unreliable for young stars ( $<300 \mathrm{Myr}$ ), but out of those 17 stars, only one star is in that age range. When several chromospheric ages are available, we favored the ages in Eiroa et al. (2013) over those in Vican et al. (2012) because the latter were based on a literature search, whereas the former were derived using spectra obtained by the DUNES team and their internally consistent estimates of Ca iI activity index (out of the 162 chromospheric ages used, 107 come from Eiroa et al. 2013). Stars without estimated ages were excluded from our analysis.
We do not include A-type stars in this study because the planet searches around these targets are preferentially done around evolved A-type stars (classes III, III-IV, and IV) with lower jitter and narrower absorption lines (Johnson et al. 2011), whereas the A-type stars targeted by DEBRIS are main-sequence (class V). Therefore, we do not have information on planet presence for most A-type stars in the DEBRIS survey. Regarding M-type stars, 89 were observed by DEBRIS, three harboring planets, one of which is also harboring a debris disk (GJ 581—Lestrade et al. 2012). We do not include M-type stars in this study because of low number statistics and because they might probe into a different regime of planetesimal and planet formation than the FGK-type stars.

The DEBRIS and DUNES surveys include single and binary/multiple stars. Previous studies indicate that there are differences in both disk frequency and planet frequency

[^0]between singles and binaries, and these could introduce a bias in our statistical analysis. Regarding disk frequency, Rodriguez \& Zuckerman (2012) found that, out of a sample of 112 mainsequence debris disk stars, $25 \pm 4 \%$ were binaries, significantly lower than the expected $50 \%$ for field stars, with a lack of binary systems at separations of $1-100 \mathrm{AU}$; for the debris disk hosts in the DEBRIS sample, the multiplicity frequency is ~28\% (D. R. Rodriguez et al. 2015, in preparation). Regarding planet frequency, Eggenberger et al. $(2007,2011)$ carried out a survey with VLT/NACO to look for stellar companions around 130 nearby solar-type stars and found that the difference in binarity fraction between the nonplanet hosts and the planet hosts is $13.2 \pm 5.1 \%$ for binary separations $<100 \mathrm{AU}$. In a more recent study, Wang et al. (2014) compared the stellar multiplicity of field stars to that of a sample of 138 bright Kepler multiplanet candidate systems, finding also that, for the planet hosts, the binary fraction is significantly lower than field stars for binary semimajor axes $<20 \mathrm{AU}$. An additional observation is that, even within the giant planet regime, binaries tighter than 100 AU show a different distribution of masses, suggesting a different formation mechanism and/or dynamical history (Duchene 2010). In view of all these studies, we have excluded from our samples 96 binary systems with semimajor axis $<100 \mathrm{AU}$ to avoid introducing a bias in our analysis. In doing that, we are naturally excluding all circumbinary disks (Kennedy et al. 2012b; D. R. Rodriguez et al. 2015, in preparation), limiting our analysis to those that are circumstellar. This seems appropriate because one would expect that the degree to which the dust is affected by planets (if present) is different, whether the dust is circumbinary or circumstellar, and this could again bias any potential planetdisk correlation.

Differences in infrared background levels could introduce a bias to the debris disk detection; however, both the DUNES and DEBRIS surveys excluded targets that were predicted to be in regions with high contamination from galactic cirrus. ${ }^{23}$ In

Note.
${ }^{\text {a }}$ Projected binary separation from D. R. Rodriguez et al. (2015, in preparation).
addition, all the targets in Set 1 have been inspected to exclude, to the best of our knowledge, sources subject to confusion.

The total number of stars in Set 1 (FGK stars within 20 pc , ages $>100 \mathrm{Myr}$ and no binary companions at $<100 \mathrm{AU}$ ) is 204. All the other star samples discussed in the subsections below are extracted from Set 1, i.e., they fulfill the same criteria with respect to stellar type, distance, age, absence of close binary companions, and nearby confusion.

Table 4 lists the planetary systems found within Set 1 . There are 22 stars harboring planets and an additional three with unconfirmed planetary systems, namely HD 22049 ( $\epsilon$ Eri), HD 10700 ( $\tau$ Cet), and HD 189567.

Even though the targets are located at a range of distances (see Figure 1), we do not expect this to introduce a significant bias to the planet-debris disk correlation study presented in this paper for the following reasons. Regarding planet detection, the Doppler studies do not depend on distance (although their sensitivity depends on $V$ magnitude and spectral type, and this may account for the closer distances of stars hosting low-mass planets only). Regarding debris disk detection, (a) the DUNES observations are designed to always reach the stellar photosphere at $100 \mu \mathrm{~m}$ to a uniform signal-to-noise ratio $>5$; (b) we assess the planet-debris correlation using survival analysis that takes into account the upper limits from the DEBRIS survey; and (c) we use a distance-independent variable, the dust excess flux ratio $\left(F_{\mathrm{obs}}^{100}-F_{\text {star }}^{100}\right) / F_{\text {star }}^{100}$, where $F_{\mathrm{obs}}^{100}$ is the observed flux at $100 \mu \mathrm{~m}$, and $F_{\text {star }}^{100}$ is the expected photospheric value at that wavelength.

### 2.2. Set 2: No-planet Sample

Set 2 is the subset of stars from Set 1 without known planets, as of 2014 August. The number of stars in this set is 182 (179 if including the three unconfirmed planetary systems).

### 2.3. Set 3: High-mass Planet Sample

Set 3 is the subset of stars from Set 1 known as of 2014 August to harbor one or more planets with masses $>30 M_{\oplus}$ ( $>0.094 M_{\text {Jup }}$ ). We call this the high-mass planet sample. The
planetary system properties are listed in Table 4. The number of stars in this set is 16 ( 17 if including the three unconfirmed planetary systems). Note that some of these systems also harbor low-mass planets. We chose this limiting planet mass because for stars harboring planets $>30 M_{\oplus}$, there is a correlation between the presence of planets and stellar metallicity (Santos et al. 2004; Fisher \& Valenti 2005). On the other hand, for stars harboring planets $<30 M_{\oplus}$, there is no correlation between the presence of planets and stellar metallicity (Ghezzi et al. 2010; Mayor et al. 2011). This might indicate differences in the planet formation mechanism that may affect the planet-debris disk correlation. We further divide this set into two subsets: 3 a (for planets with $a>0.1 \mathrm{AU}$ ) and 3 b (for planets with $a<0.1 \mathrm{AU}$ ).

### 2.4. Set 4: Low-mass Planet Sample

Set 4 is the subset of stars from Set 1 known as of August 2014 to harbor one or more planets with masses $<30 M_{\oplus}$ and no higher-mass planets. We call this the low-mass planet sample. There are six stars in this set (eight if including the three unconfirmed planetary systems).

### 2.5. Set 5: Debris Disk Sample

Due to the wavelength coverage of the DUNES and DEBRIS surveys ${ }^{24}$, this study is focused on the $100 \mu \mathrm{~m}$ emission. Set 5 is the subset of 29 stars from Set 1 with debris disks detected by Herschel at $100 \mu \mathrm{~m}$, i.e., stars for which signal to noise ratio of the excess emission, $\mathrm{SNR}_{\text {dust }}>3$, where $\mathrm{SNR}_{\text {dust }}=\frac{F_{\text {obs }}^{100}-F_{\text {star }}^{100}}{\sqrt{\sigma_{\text {obs }}^{102}+\sigma_{\text {star }}^{1002}}}$, and $F_{\text {obs }}^{100}$ and $F_{\text {star }}^{100}$ are the observed flux at $100 \mu \mathrm{~m}$ and the estimated photospheric flux, respectively, whereas $\sigma_{\mathrm{obs}}^{100}$ and $\sigma_{\mathrm{star}}^{100}$ are their $1 \sigma$ uncertainties. The $70 \mu \mathrm{~m}$ Spitzer observations do not identify any additional debris disks within Set 1. This indicates that the $100 \mu \mathrm{~m}$

${ }^{\text {c }}$ Unconfirmed planetary systems are HD 22049 ( $\epsilon$ Eri), HD 10700 ( $\tau$ Cet), and HD 189567.

Figure 1. Distribution of distances. Top: stars without known planets (Set 2). Middle: the line-filled colored histograms correspond to the high-mass planet sample (Set 3; in red, with hatching from the top left to the bottom right), lowmass planet sample (Set 4; in green, with vertical hatching), and debris disk sample (Set 5; in blue, with hatching from the top right to the bottom left). Bottom: cumulative fraction of distances (same color code as above).
emission is a good tracer of the cold KB-like dust, and we will use it as our reference wavelength. The analysis presented in this paper is limited to cold KB-like debris disks (where cold refers to debris disks detected at $70-100 \mu \mathrm{~m}$ ); we are not including the warm debris disks identified by Spitzer at $24 \mu \mathrm{~m}$ and with no excess at $70 \mu \mathrm{~m}$ (under this category there is only one planet-bearing star, HD 69830).

Note that there are several targets harboring debris disks and/ or planets that were observed with Spitzer but were not observed by the Herschel DEBRIS and DUNES surveys because of their high level of background emission.

### 2.6. Sets 6 and 7: Single-/Multiple-planet Sample

Set 6 is the subset of stars from Set 1 known as of August 2014 to harbor single-planet systems, whereas Set 7 is the subset of stars with multiple known planets.

### 2.7. Sets $1 y-5 y$ and $10-5 o$ : Young/Old Samples

If debris disks evolve with time, and the samples compared have different age distributions, this will introduce a bias in our analysis. We therefore divide the samples into stars younger
than 1 Gyr (labeled as Sets $1 \mathrm{y}-5 \mathrm{y}$ ) and stars older than 1 Gyr (Sets 10-5o; our sample has no hot Jupiters in Set 3o), limiting the comparison to sets of similar ages (i.e., within the o or y groups). We find that the distribution of ages in the samples considered (Figure 2) show that planet-bearing stars (Sets 3 and 4) tend to be older on average than the stars in the noplanet sample (Set 2); this is because Gyr-old stars have low magnetic activity, implying lower levels of radial velocity jitter that facilitate the Doppler studies. While this might result in planet-bearing stars having fewer debris detections if debris levels decrease with age, Figure 2 shows little evidence for evolution in disk detectability with time, and this is discussed further in Section 3.1.

### 2.8. Sets 1h and 1l: High-/Low-metallicity Samples

To explore the role of stellar metallicity, we divide Set 1 into two subsamples, a high-metallicity sample (Set 1 h ) and a lowmetallicity sample (Set 11), using the midpoint of the metallicity distribution of Set $1,[\mathrm{Fe} / \mathrm{H}]=-0.12$, as the dividing value.

## 3. DEBRIS DISK FREQUENCY AND DUST FLUX RATIO

The observed debris disk frequencies are listed in Tables 5-7. Due to the small sample size, the statistical uncertainties are calculated using a binomial distribution rather than the $\sqrt{N}$ Poisson uncertainty (see the appendix of Burgasser et al. 2003). Table 5 shows that the control sample (Set 1) has a debris disk frequency of $0.14_{+0.03}^{-0.02}$, similar to that found by the Spitzer surveys at $70 \mu \mathrm{~m}$ (Hillenbrand et al. 2008; Trilling et al. 2008; Carpenter et al. 2009). This result is also in agreement with Gaspar et al. (2013) who found a Spitzer incidence rate of $17.5 \%$ within the DUNES sample.

### 3.1. Dependence on Stellar Age

If debris disks evolve with time, and the samples compared have different age distributions within the decay timescale, this will introduce a bias in the comparison of the debris disk frequencies and dust flux ratios. As mentioned above, Figure 2 indicates that planet-bearing stars (Sets 3 and 4) tend to be older on average than the stars in the control samples because they are preferentially targeted by the Doppler studies.

To test for disk evolution, we divide the samples into stars with ages $0.1-1 \mathrm{Gyr}$ (labeled as Sets $1 \mathrm{y}-5 \mathrm{y}$ ) and stars older than 1 Gyr (Sets $1 \mathrm{o}-5 \mathrm{o}$ ). We then compare the disk frequencies and dust flux ratios in the young and old samples, Sets 2 y and 20 (lines 9 and 14 in Table 5). We do this exercise in the noplanet sample to minimize the effect of planet presence, as the goal is to check for disk evolution alone. Comparing Set 2 y (with a disk frequency of $7 / 46=0.15$ ) and Set 20 (with a disk frequency of $16 / 126=0.13$ ) and using a binomial distribution, we find that detecting seven or more disks in Set 2 y , when the expected detection rate is 0.13 (taking Set 20 as reference, i.e., the expected number of disk detections is $0.13 \cdot 46$ ), is a $39 \%$ probability event ( $24 \%$ if including the unconfirmed planetary systems-Table 8 , lines 1 and 2 ). This probability is not low enough to claim that the higher incidence rate in the young sample compared to the old sample is significant.
The latter, however, does not take into account the uncertainty in the expected rate of the reference sample (in this case, Set 2o). The Fisher exact test is more appropriate in this regard. To carry out this test, we classify the stars in the

Figure 2. Distribution of stellar ages. Top: stars without known planets (Set 2). Middle: the line-filled colored histograms correspond to the high-mass planet sample (Set 3; in red, with hatching from the top left to the bottom right), lowmass planet sample (Set 4; in green, with vertical hatching) and debris disk sample (Set 5; in blue, with hatching from the top right to the bottom left). Bottom: cumulative distribution of stellar ages (same color code as above).
two samples in two categories regarding disk presence: stars with disks $\left(\mathrm{SNR}_{\text {dust }}>3\right)$ and without disks $\left(\mathrm{SNR}_{\text {dust }}<3\right)$. The null hypothesis in this case is that both sets ( 2 y and 2o) are equally likely to harbor disks. The test gives a $60 \%$ probability to find the observed arrangement of the data if the null hypothesis were true (Table 8 , lines 3 and 4 ). Note that the Fisher exact test can only reject the null hypothesis, never prove it true. The Fisher exact test in this case does not identify any evolution in disk frequency within the timescale considered.

A variable that is commonly used to characterize the strength of the disk emission is the dust flux ratio, $\left(F_{\mathrm{obs}}^{100}-F_{\mathrm{star}}^{100}\right) / F_{\mathrm{star}}^{100}$, where $F_{\mathrm{obs}}^{100}$ is the observed flux at $100 \mu \mathrm{~m}$ and $F_{\text {star }}^{100}$ is the expected photospheric value at that wavelength. Table 3 lists the observed dust flux ratio for all the stars in our study. The $3 \sigma$ upper limits (preceded by a " $<$ " symbol) are given for stars without significant detected emission and are calculated assuming the observed flux is $F_{\mathrm{obs}}^{100}+3 \sigma_{\mathrm{obs}}^{100}$, for stars with $0<F_{\mathrm{obs}}^{100} / \sigma_{\mathrm{obs}}^{100}<3$, and $3 \sigma_{\mathrm{obs}}^{100}$, for stars with $F_{\mathrm{obs}}^{100} / \sigma_{\mathrm{obs}}^{100}<0$.

Figure 3 shows the cumulative distribution of the dust flux ratio, whereas Figure 4 shows its dependency with stellar age. To assess quantitatively whether the data show a decay with time, we carry out survival analysis. This is favored over the $\mathrm{K}-\mathrm{S}$ test because the latter does not deal with upper limits, and

Notes.
${ }^{\text {a }}$ Unconfirmed planetary systems are HD 22049 ( $\epsilon$ Eri), HD 10700 ( $\tau$ Cet), and HD 189567.
${ }^{\mathrm{b}}$ The statistical uncertainties are calculated using a binomial distribution.
a significant number of the targeted stars have $F_{100} / \sigma_{100}<3$ (see Table 3 and down-facing arrows in Figure 4). Using ASURV 1.2 (Lavalley et al. 1992), which implements the survival analysis methods of Feigelson \& Nelson (1985), we carried out the univariate, nonparametric two-sample Gehan, logrank, and Peto-Prentice tests to compute the probability that Sets $1 y$ and 10 have been drawn from the same parent distribution with respect to the dust flux ratio. The results are listed in Table 8 , line 5 . The logrank test is more sensitive to differences at low values of the variable (i.e., near the upper limits), whereas the Gehan test is more sensitive to differences at the high end (i.e., at the detections; Feigelson \& Nelson 1985). The Peto-Prentice test is preferred when the upper limits dominate and the sizes of the samples to be compared differ. The probabilities are not low enough to claim definitively that the two sets have been drawn from different distributions in terms of the dust flux ratio. However, given that they are in the $3-11 \%$ range to assess the role of planet presence, we will take the conservative approach of limiting the comparison of disk frequencies and dust flux ratios to stars with ages $>1$ Gyr (i.e., within Set 1o).

### 3.2. Dependence on Planet Presence

### 3.2.1. High-mass Planets

To assess the effect of high-mass planets on the presence of debris disks, we compare the disk frequencies in Set 30 (3/

Notes.
${ }^{\text {a }}$ Excluding unconfirmed planetary systems around HD 22049 ( $\epsilon$ Eri), HD 10700 ( $\tau$ Cet), and HD 189567.
${ }^{\mathrm{b}}$ The statistical uncertainties are calculated using a binomial distribution.
$14=0.21)$ and Set $20(16 / 126=0.13)$, limiting, for the reasons explained above, the comparison to the stars older than 1 Gyr . Using a binomial distribution, we find that detecting three or more disks in Set 30 when the expected detection rate is 0.13 (taking Set 20 as reference, i.e., the expected number of disk detections is $0.13 \cdot 14$ ) is a $27 \%$ event; the probability drops to $9 \%$ if including the unconfirmed planetary systems (Table 8, lines 9 and 10). Based on these numbers, there is no evidence that debris disks are more common around stars harboring highmass planets compared to the average population, in agreement with previous studies based on Spitzer observations (MoroMartín et al. 2007a; Bryden et al. 2009; Kóspál et al. 2009).

Classifying the stars in both samples (Sets 2 o and 30) into stars with and without disks and using the Fisher exact test, we find that there is a $41 \%$ probability to find the observed arrangement of the data if the null hypothesis were true, where the null hypothesis in this case is that the stars with at least one giant planet (Set 30) and the stars without known-planet planets (Set 2 o ) are equally likely to harbor disks. This probability is $11 \%$ if including the unconfirmed planetary systems (Table 8, lines 11 and 12). The Fisher exact test, therefore, does not identify any correlation between debris disk frequency and high-mass planet presence. To test how different the disk frequencies would have to be for a correlation to be identified by the Fisher exact test, we carry out the test using

Set 20 and a hypothetical Set 3o, varying in the latter the number of stars with and without disks: we find that the disk frequency for Set 30 would have to be about 2.8 times higher than in Set 2o. The identification of smaller differences in disk frequencies by the Fisher exact test is limited by low-number statistics.

Using survival analysis, we address whether the dust flux ratio, $F_{\text {dust }}^{100} / F_{\text {star }}$, is affected by the presence of high-mass planets. Figures 5 and 6 show the distribution of the dust flux ratio. The results from survival analysis (Table 8-lines 15 and 16) indicate that there is a high probability that the high-mass planet sample (Set 3o) and the no-planet sample (Set 2o) have been drawn from the same population in terms of the dust flux ratio at $100 \mu \mathrm{~m}$ (and the result holds if we include the unconfirmed planetary systems). The data do not show evidence that the disks around high-mass planet-bearing stars harbor more dust than those without known planets but with similar stellar characteristics.

### 3.2.2. Low-mass Planets

We now repeat the exercise above for the low-mass planet sample, comparing the disk frequency in $\operatorname{Set} 4 \mathrm{o}(2 / 6=0.33)$ to that in Set $20(16 / 126=0.13)$. Using a binomial distribution, we find that detecting two or more disks in Set 40 when the expected number of disk detections is $0.13 \cdot 6$ (taking Set 20 as

## Notes.

a Including unconfirmed planetary systems? " N " if those stars are included in the no-planet sample Set 2. "Y" if they are considered planet hosts (i.e., they are included in Sets 3 or 4 and 6 or 7).
${ }^{\mathrm{b}} N_{A}^{\text {tot }}$ and $N_{B}^{\text {tot }}$ are the total number of stars in each set (detections and nondetections). The number in parenthesis ( $N_{A}^{\text {upl }}$ and $N_{B}^{\text {upl }}$ ) is the number of stars in each respective set with upper limits (i.e the number of stars with nondetections for which $F_{\mathrm{obs}}^{100} / \sigma_{\mathrm{obs}}^{100}<3$ ).
${ }^{c}$ Results from the univariate, nonparametric two-sample Gehan, logrank, and Peto-Prentice tests, indicating the probability that Sets A and B have been drawn from the same population in terms of the variable under consideration.
${ }^{\mathrm{d}} \mathrm{K}-\mathrm{S}$ test probability. This is the probability that the cumulative distributions of the variable under consideration in Sets A and B differ by more than the observed value $D$, where $D$ is a measure of the largest difference between the two cumulative distributions. A small probability implies that the distributions could be significantly different.
${ }^{\mathrm{e}}$ Fisher exact test two-tail probability.
${ }^{\mathrm{f}}$ Using Poisson statistics, this is the cumulative probability of finding $x$ or more disk detections (where $x$ is the number of disk detections in Set B), when the expected rate is that of Set A.
${ }^{\mathrm{g}}$ Using a binomial distribution, this is the probability of finding $x$ or more disk detections (where $x$ is the number of disk detections observed in Set B), when the expected rate is that of Set A.
${ }^{\mathrm{h}}$ The Fisher exact test is calculated by dividing the samples into two groups: a high metallicity with $[\mathrm{Fe} / \mathrm{H}]>-0.12$ and a low metallicity with $[\mathrm{Fe} / \mathrm{H}] \leqslant-0.12$. The result is the probability that Sets A and B are equally likely to have the same distribution of high versus low $[\mathrm{Fe} / \mathrm{H}]$.
${ }^{i}$ The Fisher exact test is calculated by dividing the samples into two groups: debris disk hosts, with a signal-to-noise ratio of the excess emission $\mathrm{SNR}_{\text {dust }}=\frac{F_{\text {obs }}^{100}-F_{\text {star }}^{100}}{\sqrt{\sigma_{\text {obs }}^{100^{2}}+\sigma_{\text {star }}^{100^{2}}}}>3$, and nondebris disk hosts, with $\mathrm{SNR}_{\text {dust }}<3$. The result is the probability that Sets A and B are equally likely to harbor debris disks.

## Notes.

${ }^{\text {a }} T_{\text {dust }}^{\text {cold }}$ and $R_{\text {dust }}^{\text {cold }}$ for the stars with $100 \mu \mathrm{~m}$ excesses, calculated following Kennedy et al. (2012a, 2012b), using the full spectral energy distribution.
reference) is a $18 \%$ probability event; the probability drops to $5 \%$ if including the unconfirmed planetary systems (Table 8, lines 17 and 18). Based on these numbers there is no firm evidence that debris disks are more common around stars

Figure 3. Cumulative frequency of the dust flux ratio at $100 \mu \mathrm{~m}$. Top: only for the stars with significant detected emission (i.e., $F_{100} / \sigma_{100}>3$-this panel is biased to large excesses because for stars with faint photospheres, they can be included only if they have large dust flux ratios). Bottom: for all the stars assuming an optimistic case, where the adopted flux ratio for the targets without significant detected emission is its corresponding upper limit, and a pessimistic case, where the adopted flux ratio is 0 . Black is for the stars with ages $>1 \mathrm{Gyr}$ (Set 10), and red is for stars with ages $<1$ Gyr (Set 1y).
harboring low-mass planets compared to the average population. This test, however, does not take into account the uncertainty in the expected rate of the reference sample.

Figure 4. Top: dust flux ratio at $100 \mu \mathrm{~m}$ as a function of stellar age. The circles correspond to detections (i.e., $F_{100} / \sigma_{100}>3$ ), whereas the downfacing arrows correspond to upper limits (i.e., $\left.F_{100} / \sigma\left(F_{100}\right)<3\right)$. Black is for the stars without known planets (Set 2), red is for the high-mass planet sample (Set 3), and green is for the low-mass planet sample (Set 4). Unconfirmed planetary systems appear in orange. The larger open blue circles indicate which of those stars harbor excess emission at $100 \mu \mathrm{~m}$ (Set 5). Bottom: same as above but for the fractional luminosity, assuming a blackbody emission from the excess. The circles correspond to dust detections (i.e., stars with $\mathrm{SNR}_{\text {dust }}>3$, where $\mathrm{SNR}_{\text {dust }}=\frac{F_{\text {obs }}^{100}-F_{\text {star }}^{100}}{\sqrt{\sigma_{\text {obs }}^{100^{2}}+\sigma_{\text {star }}^{100^{2}}}}$,, whereas the down-facing arrows correspond to upper limits (i.e., SNR dust $<3$ ).

The Fisher exact test gives in a $19 \%$ probability to find the observed arrangement of the data if the null hypothesis were true, where the null hypothesis is that the stars with low-mass planets only (Set 4o) and the stars without planets (Set 2o) are equally likely to harbor disks. The probability drops to $7 \%$ when including the unconfirmed planetary systems (Table 8, lines 19 and 17). We find that the disk frequency for Set 40 would have to be about four times higher than in Set 20 in order for the Fisher exact test to identify a correlation in our small subsample, Set 4o. The identification of smaller differences in disk frequencies is limited by low-number statistics.

The results from survival analysis (Table 8-lines 23 and 24) indicate that the probability that the low-mass planet sample (Set 4o) and the no-planet sample (Set 2o) have been drawn from the same population in terms of the dust flux ratio at $100 \mu \mathrm{~m}$ is not low enough to claim a correlation (even when including the unconfirmed planetary systems). However, in this case, survival analysis might be unreliable because of the small sample size $(\mathrm{N} \lesssim 10)$ of the low-mass planet sample.

In Section 5.2 below we discuss that there are hints that the debris disk frequency around F-type stars might be higher than around G- and K-type, although this trend is not found to be statistically significant. However, given that none of the F-type stars in our sample harbor planets (see Figure 11, because it is not possible to search to such low masses around them), to be conservative we now compare the low-mass planet sample to a control sample that does not include F-type stars. We find that

Figure 5. Distribution of the excess flux ratio at $100 \mu \mathrm{~m}$ for stars with significant detected emission (i.e., $F_{100} / \sigma_{100}>3$ ). Top: the open black histogram corresponds to the stars without known planets (Set 2). Middle: the red filled histogram (with hatching from the top left to the bottom right) corresponds to the high-mass planet sample (Set 3), whereas the green filled histogram (with vertical hatching) corresponds to the low-mass planet sample (Set 4). Bottom: cumulative fraction (same color code as above). There are two stars outside the plotted range, one in Set 3 a with $F_{\text {dust }}^{100} / F_{\text {star }}^{100}=99.8$ and another in Set 2 with $F_{\text {dust }}^{100} / F_{\text {star }}^{100}=38.0$.
the binomial-derived probability that the disk frequencies of the low-mass planet sample and the no-planet sample (excluding the F's) are similar is $9 \%$ (compared to $14 \%$ when including the F's). The Fisher exact probability gives $12 \%$ (compared to $19 \%$ when including the F's). Therefore, our conclusion that there is no evidence of correlation does not change when excluding F-type stars.

In summary, our study does not show evidence of a correlation, but our conclusion is limited by the small sample size.

### 3.2.3. Planetary System Multiplicity

Comparing Set 60 (single-planet sample, with a disk frequency of 0.3 ) and Set 7 o (multiple-planet sample, with a disk frequency of $2 / 10=0.20$ ) and using a binomial distribution, we find that detecting two or more disks in Set 70 , when the expected detection rate is 0.30 (taking Set 60 as reference, i.e., the expected number of disk detections is $0.30 \cdot 10$ ), is an $85 \%$ probability event (changing only slightly

Figure 6. Cumulative frequency of the dust flux ratio at $100 \mu \mathrm{~m}$. Top: only for the stars with significant detected emission (i.e., $F_{100} / \sigma_{100}>3$ ). Bottom: for all the stars assuming an optimistic case, where the adopted flux ratio for the targets without significant detected emission is its corresponding upper limit, and a pessimistic case, where the adopted flux ratio is 0 . Black is for the stars without known planets with ages $>1$ Gyr (Set 20), red is for stars harboring high-mass planets (Set 3o), and green is for those harboring low-mass planets (Set 4o). The unconfirmed planetary systems are included under Set 2 (noplanet sample).
when including the unconfirmed planetary systems-Table 8 , lines 25 and 26). The data do not show any evidence that debris disks are more or less common around stars harboring multiple-planet systems compared to single-planet systems. The same conclusion results from the Fisher exact test (Table 8, lines 27 and 28). Regarding the dust flux ratio, survival analysis results (Table 8, lines 29-34) indicate that the multipleplanet, single-planet, and no-planet samples could have been drawn from the same population in terms of the dust flux ratio at $100 \mu \mathrm{~m}$ (and the result holds if we include the unconfirmed planetary systems). The data, again, do not show evidence of any correlation between planet multiplicity and the strength of the debris disk emission.

### 3.2.4. Effect on the Characteristic Dust Temperature

We now assess whether there is any evidence that the debris disks around planet-bearing stars might be different from those around an average population of stars in terms of the characteristic dust temperature. Sets labeled with a " t " include only the stars with estimated dust temperatures (listed in Table 9). The calculation of the graybody dust temperatures is described in Kennedy et al. (2012a) based on observations with

Figure 7. Distribution of the estimated blackbody dust temperature for the stars with debris disk detections at $100 \mu \mathrm{~m}$ (i.e., $\mathrm{SNR}_{\text {dust }}>3$ ). The open black histogram corresponds to stars without known planets (Set 2t), whereas the line-filled colored histogram corresponds to stars harboring high-mass planets (Set 3 t ; in red, with hatching from the top left to the bottom right) and stars harboring low-mass planets (Set 4 t ; in green, with vertical hatching). The top panel excludes unconfirmed planetary systems $\epsilon$ Eri and $\tau$ Cet, whereas the bottom panel includes both planetary systems.
a wide wavelength coverage. Figure 7 shows the distribution of the characteristic dust temperature in the no-planet sample (Set $2 t$ ) and the planet samples (Sets 3 t and 4 t ). The $\mathrm{K}-\mathrm{S}$ test yields two values, $D$, a measure of the largest difference between the two cumulative distributions under consideration, and the probability of finding a $D$-value greater than the observed value; the latter is an estimate of the significance level of the observed value of $D$ as a disproof of the null hypothesis that the distributions come from the same parent population, that is, a small probability implies that the distributions could be significantly different. The result from the K-S test is shown in Table 8 (lines 35 and 36), showing a very high probability. The calculation of the probability is good if $N_{1} N_{2} /\left(N_{1}+N_{2}\right) \geqslant$ 4 , where $N_{1}$ and $N_{2}$ are the number of stars in each set. However, if one wants to be conservative, it might be compromised when $N<20$, as it is the case here. Based on the limited information we have so far, there is no evidence that the characteristic temperature of the debris disks around planetbearing stars differs from the rest.

## 4. CORRELATIONS WITH STELLAR METALLICITY

Figure 8 shows the distribution of stellar metallicity. To assess the correlation with metallicity, we create Sets $1 \mathrm{~m}-5 \mathrm{~m}$, constituted by stars in Sets $1-5$ with known metallicities ${ }^{25}$ from

[^3]

Figure 8. Distribution of stellar metallicities (logarithmic scale, with $[\mathrm{Fe} / \mathrm{H}]=0.0$ for solar metallicity). The open black histograms correspond to stars without known planets and with known metallicities (Set 2 m ). Top: the line-filled colored histograms correspond to stars harboring high-mass planets (Set 3 m ; in red, with hatching from the top left to the bottom right) and low-mass planets (Set 4 m ; in green, with vertical hatching). Middle: subset harboring excess emission at $100 \mu \mathrm{~m}$ (Set 5m; in blue, with hatching from the bottom left to the top right). The stars with unconfirmed planetary systems, $\epsilon$ Eri and $\tau$ Cet, are included in Set 2 m (no-planet sample). Bottom: cumulative distributions of stellar metallicities (same color code as above).

Maldonado et al. (2012) and Eiroa et al. (2013). These sets are further divided into stars with high metallicities (Sets 1h5h) and those with low metallicities (Sets 11-51), using the midpoint of the metallicity distribution, $[\mathrm{Fe} / \mathrm{H}]=-0.12$, as the dividing value. Table 6 lists how many stars are in each subset.

### 4.1. Debris Disk Presence

We now compare the debris disk frequencies in Set 1h (17/ $75=0.23)$ and Set $11(9 / 61=0.15)$. Using a binomial distribution, finding 17 or more disk detections in Set 1 h , when the expected detection rate is 0.15 (taking Set 11 as reference, i.e., the expected number of disk detections is $0.15 \cdot 75$ ), is a $4 \%$ probability event (Table 8-line 37), indicating that the disk frequencies in the high- and low-metallicity samples might differ. This result, however, does not take into account the uncertainty in the expected rate of the reference sample (in this case Set 11). From the Fisher exact test, we find that there is a $28 \%$ probability to find the observed arrangement of the data if the null hypothesis were true, where the null hypothesis in this

Figure 9. Cumulative frequency of the dust flux ratio at $100 \mu \mathrm{~m}$. Top: only for the stars with significant detected emission (i.e., $F_{100} / \sigma_{100}>3$ ). Bottom: for all the stars assuming an optimistic case, where the adopted flux ratio for the targets without significant detected emission is its corresponding upper limit, and a pessimistic case, where the adopted flux ratio is 0. Black is for the stars with metallicities larger than the average $([\mathrm{Fe} / \mathrm{H}]>-0.12$; Set 1 h$)$, and red is for the stars with lower metallicities $([\mathrm{Fe} / \mathrm{H}] \leqslant-0.12$; Set 11$)$, independently of planet presence.
case is that the stars without disks (Set 1 m -Set 5 m ) and the stars with disks (Set 5m) are equality likely to have metallicities $>-0.12$ (Table 8-line 38). From the K-S test, the probability that the no-planet sample (Set 2 m ) and the debris disk sample (Set 5m) could have been drawn from the same distribution in terms of stellar metallicity is $33 \%$ ( $39 \%$ when including unconfirmed planetary systems; Table 8lines 47-48).
Regarding the strength of the excess emission, we use survival analysis to check if the low-metallicity and highmetallicity samples could have been drawn from the same population in terms of the dust flux ratio. Figures 9 and 10 show the cumulative frequencies of the dust flux ratio and the fractional luminosity of Sets 1 h and 11 , showing that there is a dearth of debris disks with high dust flux ratios and high fractional luminosities around low-metallicity stars. However, the probabilities listed in Table 8 (line 49) indicate that this trend is not statistically significant. We cannot rule out the hypothesis that the high-metallicity and low-metallicity samples have been drawn from the same distribution in terms of the dust flux ratio. We conclude that the Fisher exact test and survival analysis do not allow us to identify any correlation between high stellar metallicity and debris disks.

Figure 10. Cumulative frequency of the dust fractional luminosity. Top: only for the stars with excess detections (i.e., stars with $\mathrm{SNR}_{\text {dust }}>3$ ). Bottom: for all the stars assuming an optimistic case, where the adopted fractional luminosity for the targets without excess detections is its corresponding upper limit, and a pessimistic case, where the adopted fractional luminosity is 0 . Black is for the stars with metallicities larger than the average $([\mathrm{Fe} / \mathrm{H}]>-0.12$; Set 1 h ), and red is for the stars with lower metallicities $([\mathrm{Fe} / \mathrm{H}] \leqslant-0.12$; Set 11 ), independently of planet presence.

### 4.2. Planet Presence

Comparing the planet and no-planet samples in terms of stellar metallicity with the Fisher exact test (Table 8-lines $39-42$ ), we find that in the case of giant planets, there is a $0.2 \%$ probability to find the observed arrangement if the stars without giant planets (Set 1 m -Set 3 m ) and the stars with giant planets (Set 3 m ) were equally likely to have metallicities $>-0.12$, whereas for low-mass planets (Set 1m-Set 4 versus Set 4), this probability is almost $100 \%$ (the result holds when including the unconfirmed planetary systems). From the K-S test, the probability that the no-planet sample and the high-mass planet sample could have been drawn from the same distribution in terms of stellar metallicity is $0.2 \%$, whereas the probability that the no-planet sample has been drawn from the same distribution as the low-mass planet sample and the debris disk sample is much larger (49\%; Table 8-lines 43-46).

## 5. POSSIBLE BIASES INTRODUCED BY THE SAMPLE SELECTION

### 5.1. Presence of Undetected Planets

We now describe the potential biases that the sample selection could introduce in the statistical analysis described above. First, we assess whether the presence of unidentified planetary systems could affect our results. If we were to have
many stars with high-mass planets in the control sample, Set 2, one could argue that a high-mass planet-debris disk correlation could have been present but hidden by all the "planet contaminants." However, because the high-mass planet frequency is small, this seems unlikely. Due to the higher frequency of low-mass planets (Mayor et al. 2009, 2011; Batalha 2014 and references therein; Marcy et al. 2014 and references therein), we probably have many stars with lowmass planets in the control sample which have not been identified. This means that a low-mass planet-debris disk correlation may still be hidden in the data. We could avoid these biases by comparing the planet sets to a subset of stars in Set 2 for which the presence of planets within a given period and mass has been ruled out by the radial velocity surveys. However, because nondetections are generally not made public by the planet search teams, the information to construct this noplanet stellar sample is not available.

### 5.2. Distribution of Spectral Types

By considering FGK stars to assess the planet-debris disk correlation, we are implicitly assuming that the disk frequency and the planet frequency do not differ significantly among these spectral types.
Table 7 and Figure 11 show the distribution of spectral types in the samples under consideration. Let us limit the comparison to stars older than 1 Gyr (to avoid biases due to disk evolution), i.e., to the stars in Set 10 (Table 7-line 6). For the F-stars, the disk fraction is 0.24 ( $8 / 33$ disk detections): using a binomial distribution, finding eight or more disk detections, when the expected detection rate is 0.14 (taking the disk frequency of the G-stars as reference, i.e., when the expected number of disk detections is $0.14 \cdot 33$ ), is an $8 \%$ probability event. Whereas for the K-stars, with a disk fraction of 0.09 ( $6 / 64$ disk detections), using a binomial distribution, finding six or more disk detections, when the expected detection rate is 0.14 , is a $90 \%$ probability event. If we were to take the disk frequency of Ktype as reference, for the F-stars, finding eight or more disk detections, when the expected detection rate is 0.09 (expected number of disk detections of $0.09 \cdot 33$ ), would be a $0.8 \%$ event (Table 8-lines 50-52). The latter seems to indicate there is a significant difference in disk frequencies between K-type and F-type stars.

Eiroa et al. (2013) found that the frequency of disks in the DUNES survey does not change significantly among FGK stars. The increased disk frequency for F-type stars found in our sample might have been biased to some degree by the shallower integration time of some of the DEBRIS targets, although the different $T_{\text {eff }}$ distribution for the stars in the DEBRIS and DUNES surveys may also play a role (the former covering all FGK stars, whereas the latter covers mid-F to midK. ${ }^{26}$ Using a larger sample of Spitzer and Herschel observations, Sierchio et al. (2014) found no significant dependence with spectral type in the F4-K4 range.
The test above does not consider the uncertainty in the expected rate of the reference sample. Classifying the stars into those with and without debris disks and applying the Fisher exact test, we find that in this case the probability is not low enough to disprove the null hypothesis that the F-stars are

[^4]

Figure 11. Distribution of spectral types for the different sets.
equally likely to harbor disks as are the $\mathrm{G}+\mathrm{K}$ stars (Table 8lines 53 and 54).

Regarding planet frequency, Doppler surveys indicate there is a correlation between high-mass planet frequency and spectral type that follows roughly a linear increase with stellar mass (Johnson et al. 2010). From a compilation of Doppler surveys, Gaidos et al. (2013) suggest $\mathrm{f}(\%)=-1.11+$ $5.33 M_{\text {star }} / M_{\odot}$, for planets $>8 R_{\oplus}$ (masses $>95 M_{\oplus}$-see their Figure 8). For low-mass planets in the $0.8-6 R_{\oplus}$ range, Kepler data indicate that among the FGK stars the planet frequency

Figure 12. Cumulative frequency of the dust fractional luminosity. Top: only for the stars with excess detections (i.e., stars with $\mathrm{SNR}_{\text {dust }}>3$ ). Bottom: for all the stars assuming an optimistic case, where the adopted fractional luminosity for the targets without excess detections is its corresponding upper limit, and a pessimistic case, where the adopted fractional luminosity is 0 . Black is for the stars without known planets with ages $>1 \mathrm{Gyr}$ (Set 2o), red is for stars harboring high-mass planets (Set 3o), and green is for those harboring low-mass planets (Set 4o). The unconfirmed planetary systems are included under Set 2 (no-planet sample).
does not depend significantly on the spectral type (Fressin et al. 2013). Table 7 and Figure 11 indicate that neither the high-mass nor low-mass planet frequencies within our sample reflect the above trends, with a higher incidence around G-type stars mostly likely because fewer F and Ks were searched for planets. This might skew slightly the disk incidence rate comparison for high-mass planets. Again, because nondetections are generally not made public, there is no way to circumvent this issue.
In Section 7.6 we discuss how the conclusions change when excluding F-type stars from our analysis.

## 6. FRACTIONAL LUMINOSITIES AND COMPARISON TO THE SOLAR SYSTEM'S DEBRIS DISK

Figure 12 shows the cumulative frequency of the dust fractional luminosity. This variable is commonly used to characterize debris disk emission because it allows comparison of disks observed at different wavelengths; it is not very modeldependent as long as the wavelength coverage is good (as is the case in our samples). For stars with dust excess detections $\left(\mathrm{SNR}_{\text {dust }}>3\right)$, the fractional luminosity is calculated following Kennedy et al. (2012a, 2012b). For stars with dust excess nondetections $\left(\mathrm{SNR}_{\text {dust }}<3\right)$, the $3 \sigma$ upper limit to the fractional luminosity is calculated from

Figure 13. Cumulative frequency of the fractional luminosity. The thick black histogram corresponds to the stars with ages $>1$ Gyr independently of planet presence (Set 10). Because we are interested in the cumulative frequency of the stars for fractional luminosities greater than the minimum observed value, in calculating the cumulative distribution we adopt the pessimistic case, where the fractional luminosity for the stars without excess is 0 . The blue, green, magenta, and red lines correspond to theoretical distributions that assume a Gaussian distribution of fractional luminosities in logarithmic scale, with average values of $10 \times, 3 \times, 1 \times$, and $0.1 \times$ that of the solar system, respectively, and assuming for the solar system a fractional luminosity of $10^{-6.5}$. We fixed the cumulative frequency of disks with $L_{\text {dust }} / L_{*}>10^{-5}$ at $10 \%$ according to the observed result (in set 10), implying $1 \sigma$ widths for the theoretical distributions of $0.4,0.8,1.18$, and 2.0 for the blue, green, magenta, and red lines, respectively. Top: showing only the detected range; there are only three targets with fractional luminosities below $8 \times 10^{-6}$, compromising the fit to the data in that low range because of low-number statistics. Bottom: the dotted line that coincides with the solid line corresponds to the the pessimistic case, where the adopted fractional luminosities for the targets without excess detections are taken to be 0 , whereas the second dotted line on the upper part of the panel corresponds to the optimistic case, for which the upper limits are adopted.
$\frac{L_{\text {dust }}}{L_{\text {star }}}=\left(\frac{T_{\text {dust }}}{T_{\text {star }}}\right)^{4}\left(\frac{e^{x \text { dust }}-1}{e^{x_{\text {star }}}-1}\right) F_{\text {obs }}^{100}-F_{\text {star }}^{100}-F_{\text {star }}^{100}$ following Equation (4) in Beichman et al. (2006), and assuming the observed flux is $F_{\mathrm{obs}}^{100}+3 \sigma_{\mathrm{obs}}^{100}$, for stars with $F_{\mathrm{obs}}^{100} / \sigma_{\mathrm{obs}}^{100}>0$, and $3 \sigma_{\mathrm{obs}}^{100}$, for stars with $F_{\mathrm{obs}}^{100} / \sigma_{\mathrm{obs}}^{100}<0$. In this expression, $x=\frac{h \nu}{k T}$, where $\nu$ is the frequency corresponding to $100 \mu \mathrm{~m}, T_{\text {star }}=T_{\text {eff }}$ is the effective stellar photospheric temperature, and $T_{\text {dust }}$ is assumed to be 50 K (as in Eiroa et al. 2013).

The fractional luminosity can help place the debris disk observations in this study in the context of the solar system's debris disk. Following Bryden et al. (2006), we compare the observed cumulative distribution of fractional luminosity to those expected from Gaussian distributions in logarithmic scale, with average values of $10 \times, 3 \times, 1 \times$, and $0.1 \times$ that of the solar system's debris disk, assuming for the latter a fractional
luminosity of $10^{-6.5}$. To avoid biases due to disk evolution, we limit the comparison to stars older than 1 Gyr (Set 10). The observed and Gaussian-derived cumulative distributions are shown in Figure 13. The bottom panel shows that the blue line exceeds the most optimistic case at low fractional luminosities. This means that we can reject the hypothesis that the median of the disk fractional luminosity is 10 times that of the solar system's debris disk, in agreement with Bryden et al. (2006). The best fit to the data is a Gaussian centered on the solar system value (magenta line in the top panel). This result is discussed in Section 7.7.

## 7. SUMMARY AND DISCUSSION

We have carried out a statistical study of an unbiased subsample of the Herschel DEBRIS and DUNES surveys, consisting of 204 FGK stars located at distances $<20 \mathrm{pc}$, with ages $>100 \mathrm{Myr}$ and with no binary companions at $<100 \mathrm{AU}$. The main goal is to assess whether the frequency and properties of debris disks around a control sample of FGK stars are statistically different from those around stars with high-mass and low-mass planets. We find the following results.

### 7.1. Disk Evolution

The Spitzer surveys found that the upper envelope of the $70 \mu \mathrm{~m}$ debris disk emission shows a decline over the $\sim 100 \mathrm{Myr}$ of a star's lifetime, indicating that there might be a population of rapidly evolving disks that disperse by 100 Myr . Our sample does not show clear evidence of disk evolution on the gigayear timescale. This is in agreement with the lack of disk evolution observed at $70 \mu \mathrm{~m}$ in Spitzer surveys for stars older than $1 \mathrm{Gyr}^{27}$ (Hillenbrand et al. 2008; Trilling et al. 2008; Carpenter et al. 2009). In a recent study, using both Spitzer and Herschel observations, and using a sample 2.5 times larger than ours, Sierchio et al. (2014) found that for disks with fractional luminosities smaller than $10^{-5}$ there is a significant decrease in the debris disk frequency between 3 and 5 Gyr. To look for evidence of disk evolution in the 5 Gyr timescale that could bias our results, we have divided the sample into stars with ages $0.1-5$ Gyr (labeled as Sets 1oy and 2oy) and stars older than 5 Gyr (Sets 100 and 200). We then compare the disk frequencies and dust flux ratios in both subsamples (lines 6 and 8 in Table 8). The overall resulting probabilities are not low enough to claim that the two sets have been drawn from different distributions in terms of the dust flux ratio, nor that their disk incidence rates differ significantly. The Fisher exact test (line 7 in Table 8) also indicates that both sets are equally likely to harbor disks. We therefore do not find evidence in our restricted sample of disk evolution in the 5 Gyr timescale.

### 7.2. High-mass Planet Presence

Our sample does not show evidence that debris disks are more common around stars harboring high-mass planets compared to the average population. This is in agreement with the studies based on Spitzer observations that found no correlation between fractional luminosities, $L_{\text {dust }} / L_{\text {star }}$, and the presence of high-mass planets (Moro-Martín et al. 2007a; Bryden et al. 2009). Figure 8 in Maldonado et al. (2012) also

[^5]shows this trend, where the stars with disks and planets seem to be well mixed with stars with only disks in terms of the fractional luminosity, but they did not carry out any statistical analysis. This issue will be revisited using a larger sample that combines Herschel DEBRIS, DUNES, and SKARPS observations (G. Bryden et al. 2015, in preparation).

Overall, the lack of observed correlation between high-mass planets and debris disks was understood within the context of the core accretion model for planet formation, where the conditions to form debris disks are more easily met than the conditions to form high-mass planets. This is in agreement with the metallicity studies that indicate that there is a correlation between high-mass planets and stellar metallicity, but no correlation between debris disks and stellar metallicity. Additionally, the presence of debris disks around stars with a very wide range of properties, from M-type (Kennedy et al. 2007; Lestrade et al. 2012) to the progenitors of white dwarfs (Jura 2003, 2007), implies that planetesimal formation is a robust process that can take place under a wide range of conditions. Therefore, based on formation conditions, if planetesimals can be common in systems with and without high-mass planets, there is no reason to expect a correlation between high-mass planets and debris disks (MoroMartín et al. 2007a).

Another factor contributing to the lack of a well-defined correlation with planet presence might be that the dynamical histories likely vary from system to system, and other stochastic effects need also to be taken into account, e.g., those produced by dynamical instabilities of multiple-planet systems clearing the outer planetesimal belt (Raymond et al. 2011, 2012), the planetesimal belt itself triggering planet migration and instabilities (Tsiganis et al. 2005; Levison et al. 2011), or the stripping of planetesimals from disks during stellar flybys in the first 100 Myr , when systems are still in their dense birth cluster (Lestrade et al. 2011).

Another aspect that needs to be taken into account is that the planets detected by radial velocity surveys and the dust observed at $100 \mu \mathrm{~m}$ occupy well-separated regions of space, limiting the influence of the observed closer-in planets on the dust production rate of the outer planetesimal belt; there are long-range gravitational perturbations produced by secular perturbations from single planets on eccentric orbits (Mustill \& Wyatt 2009) or multiplanet systems (MoroMartín et al. 2007b, 2010) that allow close-in planets to excite outer planetesimal belts, but the timescale of the former may be longer than the age of the system, and the latter is limited to certain planet configurations.

### 7.3. Low-mass Planet Presence

In a preliminary study, and using a different subsample of the Herschel DEBRIS survey, Wyatt et al. (2012) identified a tentative correlation between debris and the presence of planets with masses $<95 M_{\oplus}$. Using a different subsample, Marshall et al. (2014) also found evidence that stars with planets $<30 M_{\oplus}$ are more likely to harbor debris disks than are stars with planets $>30 M_{\oplus}(6 / 11$ versus $5 / 26)$. There are aspects related to the dynamical evolution of planetary systems that could result in a higher frequency of debris disks around stars with low-mass planets compared to those with high-mass planets. Wyatt et al. (2012) discussed two alternative scenarios: (1) if the planets formed in the outer region and migrated inward, low-mass planets would have
been inefficient at accreting or ejecting planetesimals, leaving them on dynamically stable orbits over longer timescales; high-mass planets would have been more efficient at ejecting planetesimals, leaving behind a depleted population of dustproducing parent bodies. (2) Alternatively, if the planets formed in situ, the timescale for the planet to eject the planetesimals is shorter in systems with high-mass planets than with low-mass planets. However, the true migration histories of the systems studied may be significantly more complicated than the story portrayed under the two scenarios described above. For example, in our own solar system, it is now well established that the ice giants, Uranus and Neptune, migrated outward over a significant distance to reach their current locations, sculpting the trans-Neptunian population as they did so (Hahn \& Malhotra 2005).

In this paper we have used the cleanest possible sample of the Herschel DEBRIS and DUNES surveys to assess if the data at hand can confirm the tentative detection of a low-mass planet-debris correlation. Contrary to the preliminary analyses mentioned above, here we have discarded stars without known ages, with ages $<1 \mathrm{Gyr}$, and with binary companions $<100$ AU, allowing us to rule out possible correlations due to effects other than planet presence. We find that the data do not show clear evidence that debris disks are more common around stars harboring low-mass planets compared to the average population. However, having a clean sample comes at a price because the smaller sample size limits the strength of the statistical result: a positive detection of a correlation could have been detected by the Fisher exact test only if the disk frequency around low-mass planet stars were to be about four times higher than the control sample.

The planet-debris disk correlation studies can shed light on the formation and evolution of planetary systems and may perhaps help "predict" the presence of planets around stars with certain disk characteristics. Far from being a closed issue, this correlation (or lack of) needs to be revisited. In the near future, G. Bryden et al. (2015, in preparation) will address this question using a sample that combines Herschel DEBRIS, DUNES and SKARPS surveys, overcoming to some degree our limitations due to the small sample size. However, there are another two aspects that need to be improved upon and, with the data at hand, cannot be addressed at the moment: our ability to detect fainter disks and to detect or rule out the presence of lower-mass planets to greater distances.

Regarding the disk detections, our knowledge of circumstellar debris is limited: we only have detections for the top $20 \%$ of the dust distribution, assuming all stars have a remnant circumstellar disk at some level; limits closer to the KB-level are only possible for nearby F+ type stars, and we are incapable of seeing exact analogues to our own solar system leaving a large parameter space with no constraint on planet or dust properties. Future missions under consideration such as SPICA would improve things significantly: if its telescope is not descoped, the improvement in sensitivity would allow detection of photospheres not detected by Herschel, e.g., for M stars and for FGK stars at large distances; its noise would also be lower than Herschel, allowing it to detect fainter disks.

Regarding the planet detection, the high frequency of lowmass planets indicates that we probably have many low-mass planet stars in the control sample which have not been identified, hindering our ability to detect a correlation. To overcome this problem, we rely on radial velocity surveys to
gradually probe both to greater distances and lower planet masses; but also critically important is that these teams make the nondetections publicly available so we can identify systems for which the presence of planets of a given mass can be excluded out to a certain distance.

### 7.4. Planetary System Multiplicity

Dynamical simulations by Raymond et al. $(2011,2012)$ of multiple-planet systems with outer planetesimal belts indicate that there might be a correlation between the presence of multiple planets and debris. This is because the presence of the former indicates a dynamically stable environment where dustproducing planetesimals may have survived for extended periods of time (as opposed to single-planet systems that in the past may have experienced gravitational scattering events that resulted in the ejection of other planets and dust-producing planetesimals). It is of interest therefore to assess whether debris disks are correlated with planet multiplicity.

Our sample does not show evidence that debris disks are more or less common, or more or less dusty, around stars harboring multiple-planet systems compared to single-planet systems.

### 7.5. Dust Temperature

Based on the limited statistics, there is no evidence that the characteristic dust temperature of the debris disks around planet-bearing stars is any different from that in debris disks without identified planets. This is of course subject to detailed individual modeling, as the spatial dust disk distribution of the planet-bearing systems might show more structural features due to gravitational perturbations compared to the disks around stars not harboring planets, in which case it might not be appropriate to describe the dust excess emission with a single temperature.

### 7.6. Stellar Metallicity

We find that there is no evidence that debris disks are more common around stars with high metallicities. This is in agreement with previous studies (Bryden et al. 2006; Greaves et al. 2006). We find a dearth of debris disks with high dust flux ratios (also fractional luminosities) around low-metallicity stars, consistent with the model of Wyatt et al. (2007). However, survival analysis tests indicate that this trend is not statistically significant and that we cannot rule out the hypothesis that the high-metallicity and low-metallicity samples have been drawn from the same distribution in terms of the dust flux ratio.

The data confirm the well-known correlation between high metallicities and the presence of high-mass planets. On the contrary, we find no evidence of a correlation between high metallicities and the presence of low-mass planets. We therefore find the well-known positive correlation between the presence of planets and stellar metallicity for stars with high-mass planets but no correlation for stars with low-mass planets only in agreement with extensive Doppler studies (Santos et al. 2004; Fisher \& Valenti 2005; Ghezzi et al. 2010; Mayor et al. 2011). Maldonado et al. (2012) studied a larger stellar sample and derived the metallicities in a uniform way. They found an increasing correlation with stellar metallicity from stars without planets and disks and stars with debris disks to stars with high-mass planets. They also concluded that the
correlation with stellar metallicity is due to the presence of planets and not the presence of debris disks.

### 7.7. Fractional Luminosity and Comparison to the Solar System Debris Disk

Comparing the observed cumulative distribution of fractional luminosity to those expected from a Gaussian distribution in logarithmic scale, we find that a distribution centered on the solar system value (taken as $10^{-6.5}$ ) fits the data well, whereas one centered at 10 times the solar system's debris disks can be rejected.

This is of interest in the context of future prospects for terrestrial planet detection. Even though the Herschel observations presented in this study trace cold dust located at tens of AU from the star, for systems with dust at the solar system level, the dust dynamics is dominated by Poynting-Robertson drag. This force makes the dust in the outer system drift into the terrestrial-planet region. This warm dust can impede the future detection of terrestrial planets due to the contaminant exozodiacal emission, with its median level, its uncertainty, and shape of its distribution being some of the parameters that may affect the aperture size required for a telescope such as ATLAST to be able to characterize biosignatures (see, e.g., Stark et al. 2014; Brown 2015). Ruling out a distribution of fractional luminosities centered at 10 times the solar system level implies that there are a large number of debris disk systems with dust levels in the KB region low enough not to become a significant source of contaminant exozodiacal emission. Comets and asteroids located closer to the star are other sources of dust that can contribute to the exozodiacal emission (and for those, Herschel observations do not provide constraints), but planetary systems with low KB dust-type of emission likely imply low-populated outer belts leading to low cometary activity. These results, therefore, indicate that there are good prospects for finding a large number of debris disk systems (i.e., systems with evidence of harboring planetesimals) with exozodiacal emission low enough to be appropriate targets for terrestrial planet searches. Dedicated warm dust surveys with the Keck Interferometer Nuller (Millan-Gabet et al. 2011), CHARA/FLUOR (Absil et al. 2013), VLTI/ PIONIER (Ertel et al. 2014), and LBTI (under the HOSTS program) are shedding or will soon shed light on this issue.

Even though the planetesimals detected by Herschel in the far infrared are located far from the terrestrial-planet region, their presence is favorable to the growth and survival of terrestrial planets because these planetesimals indicate that the system has experienced a calm dynamical evolution, as opposed to an environment of dynamically active, high-mass planets. Such an environment would tend to destroy both the outer, dust-producing planetesimal belt and the planetesimals that might otherwise build the terrestrial planets. This conclusion was the result of Raymond et al.'s (2011, 2012) extensive dynamical simulations consisting of high-mass planet embryos and inner and outer belts of planetesimals. These simulations find that there is a strong correlation between the presence of cold dust in the outer planetary system and the presence of terrestrial planets in the inner region, so a system with low levels of KB dust emission might also imply a dynamical history not amicable to terrestrial planets. The solar system, in this case, would be an outlier, with a low-level of KB dust but a high number of terrestrial planets. It would be of great interest to extend Raymond et al.'s (2011, 2012)
simulations to cover a wider range of initial conditions to further explore this correlation, as it would enlighten the target selection for an ATLAST-type mission.

[^0]:    ${ }^{22}$ Comparing, for example, the stellar ages in Sierchio et al. (2014) to those in Vican et al. (2012), among the 48 stars that these two studies have in common, we find that differences in ages are less than $50 \%$, except for five stars: HD126660/HIP 70497 (80\%), HD23754/HIP 17651(83\%), HD189245/HIP 98470 (733\%), HD20630/HIP 15457 (70\%), and HD101501/HIP 56997 ( $84 \%$ ). The age estimations are therefore broadly consistent.

[^1]:    ${ }^{23}$ The unconfirmed planet host star $\alpha$ Cen B was observed as part of the DUNES and Hi-Gal programs, but it was excluded from this analysis because its high background level does not fulfill the DUNES and DEBRIS selection criteria, and our analysis is intended to be unbiased.

[^2]:    ${ }^{24}$ DEBRIS and DUNES utilized the simultaneous 100 and $160 \mu \mathrm{~m}$ imaging mode as the basis for their survey data, with both teams taking additional data toward selected sources using the 70 and $160 \mu \mathrm{~m}$ imaging mode of PACS and 250,350 , and $500 \mu \mathrm{~m}$ imaging with SPIRE as appropriate.

[^3]:    ${ }^{25}$ Regarding possible sources of biases due to stellar age and distance, Maldonado et al. (2012) argued that because the stars are at close distances from the Sun (in our case within 20 pc ), it is unlikely that they have suffered different enrichment histories.

[^4]:    ${ }^{26}$ The spectral type dependence of the debris disk frequency within the DEBRIS sample will be studied in more detail by B. Sibthorpe et al. (2015, in preparation).

[^5]:    ${ }^{27}$ Compared to the $70 \mu \mathrm{~m}$ observations, the $100 \mu \mathrm{~m}$ emission might also trace dust located further out, where the collision times are longer; if this second population of dust exists, one would expect even less evolution at this longer wavelength.
