ABSTRACT

We report the case of a 25-year-old woman who developed temporal lobe epilepsy associated with systemic lupus erythematosus (SLE). Serum and cerebrospinal fluid samples showed high titers of anti-ribosomal P (anti-P) antibodies with negative anti-NMDAR antibodies. She was receiving prednisone and azathioprine, with normalization of SLE serum markers, but without changes in titers of anti-P antibodies. No seizure control was achieved using valproic acid, levetiracetam and lamotrigine. However, she had a selective response to topiramate, an AMPAR blocker, maintained during 6 years of follow-up. We discuss the pathophysiology of this autoimmune epilepsy associated with high titer anti-P antibodies.

1. Introduction

Anti-ribosomal protein P (anti-P) antibodies, described three to four decades ago, have been strongly associated with neuropsychiatric symptoms in patients with systemic lupus erythematosus (SLE) (Bonfa et al., 1987). Initially, anti-P antibodies seem to recognize terminal-carboxy-residues of three ribosomal phosphoproteins, P0 (38 kD), P1 (19 kD), and P2 (17 kD) (Elkon et al., 1986). However, it has been described in mouse models that the neurons of the dentate gyrus and CA1 but not CA3, express surface antigens that are also recognized by anti-P antibodies. These antibodies affect the post-synaptic transmission increasing the activity of AMPA and NMDA receptors, altering the long-term potentiation (Segovia-Miranda et al., 2015). This particular mechanism, could be epileptogenic and lead to the appearance of epileptiform discharges in patients with SLE. On the other hand, one of the several mechanisms of action of topiramate is to inhibit glutamatergic synaptic activity, in particular by blocking AMPA (α -amino - 3 - hydroxy - 5 - methylisoxazole - 4 - propionic acid) / kainate glutamate receptors (Shank et al., 2000), and might be useful in this scenario. We report and discuss the pathophysiology of seizures associated with high titer of anti-P antibodies in a patient with refractory temporal lobe epilepsy and SLE successfully treated with topiramate.

2. Case report

We received a 25 years old female patient for pre-surgical evaluation of refractory epilepsy. She was diagnosed with SLE two years before because of skin rash and arthritis, with positive anti-DNA antibodies (32 UI/mL, range 0–15), and low C₃ (62.3 mg/dL range 70–150) and C₄ (7.3 mg/dL range 15–45). She had negative anti-nuclear antibodies (ANA), anti-RO, anti-RNP, anti-SM, anti-LA, anti-SCL-70, anti-JO-1, beta-2 glycoprotein 1, lupus anticoagulant, and anticardiolipin antibodies. High titers of anti-P were found in serum (199.7 U/mL, range 0–25) and cerebrospinal fluid (positive in a qualitative test). No pleocytosis, oligoclonal bands or elevated IgG index were observed in the cerebrospinal fluid. The patient had acute cutaneous lupus (6 points), joint involvement (6 points), anti-DNAs antibody (6 points), low C₃-C₄ (4 points), and seizures (6 points) from the ACR/EULAR classification (Aringer et al., 2019). By the time of the first assessment in our centre, she was receiving treatment with oral prednisone (5 mg QD) and azathioprine (150 mg QD), with normalization of anti-DNA antibodies and C₃ and C₄ measurements. Prednisone and azathioprine were progressively changed to hydroxychloroquine (200 mg QD). However, she had persistent positive anti-P titers, similar to those described at diagnosis (serum: 110 U/mL). She had a neuropsychological assessment showing only mild visual episodic memory deficits that recovered by the 6 and 12-month evaluation. We also

available in research labs. Infectious diseases work-up including syphilis and human immunodeficiency virus were negative. Since her SLE diagnosis, she presented 1 to 10 focal seizures per month, characterized by sudden cacosmia, dysgeusia and frequently followed by epigastralgia, autoscopia and focal seizure with impaired awareness for 1–2 min. She was already being treated with several regimens of antiepileptic drugs such as valproic acid (250 mg TID), levetiracetam (1500 mg BID), lamotrigine (50 mg per day, suspended by a rash), remaining refractory. We performed a long-term scalp electroencephalogram (EEG) monitoring (24 h) that showed right fronto-temporal spikes discharges (Fig. 1.A.) and her magnetic resonance images showed abnormal increased T2 signal and mildly increased volume of the right temporal amygdala and head of the hippocampus without abnormal gadolinium enhancement (Fig. 1.B.i).

Reviewing the pathophysiological mechanisms described in animal models, which suggest that anti-P antibodies increase synaptic glutamatergic activity, we decided to start treatment with topiramate 100 mg BID, reaching immediate seizure response (Fig. 1.C.).

The patient remained without seizures, except for a focal seizure with impaired awareness followed by bilateral spreading that occurred after stopping the topiramate for 1 week at the fifth year of treatment (*, Fig. 1.C.).

At the sixth year of follow-up, we monitored her cerebral MRI, which has remained without significant changes (Fig. B.ii, iii, iv), without signs of hippocampal body atrophy and no cortical developmental anomalies were seen in the temporal lobe. Her SLE markers remain negative but maintaining the serum high titers of anti-P antibodies (105.3 U/mL). The patient gave her informed consent for the presentation of this case.

3. Discussion

Although anti-P antibodies have been historically associated with psychosis, cognitive and affective disorders in SLE patients, one meta-analysis found that in patients whose manifestation of neuropsychiatric SLE was seizures, the presence of positive serum anti-P antibodies was 8 times more frequent than the 4 to 5 times observed in patients with psychosis or depression. Furthermore, the prevalence of positive titers of anti-P antibodies in cerebrospinal fluid increased up to 45 times over anti-neuronal antibodies and was found 10 times more frequently in the same epilepsy patients (Ho et al., 2016).

Recently, a study using rat models and electro-oscillogram showed that the intraventricular injection of IgG fraction of anti-P positive and affinity-purified anti-P antibodies provoke an increase in polyspikes, diffusely distributed in hippocampal fields and cerebral cortex. These abnormalities were antibody-specific and persistent for about a month, is associated with behavioural disorders with varying degrees of severity in every animal injected (Gaburo Jr et al., 2017).

These descriptions are in line with the pathophysiological findings of Segovia-Miranda et al. who found that affinity-purified anti-P increased the field excitatory postsynaptic potential in the dorsal hippocampus of mice and that anti-P antibodies increased the amplitude of spontaneous AMPAR-mediated currents in primary spinal cord neurons recorded in the whole-cell patch-clamp, in a dose-dependent way. For these reasons, we decided to start antiepileptic treatment with topiramate, which most important mechanism of action consists in blocking

performed anti-NMDA receptor antibodies which were negative. No other panels for autoimmune encephalitis were accessible at that time in our country, and the patient was unable to cost any other studies

the AMPA receptor, producing a fast and complete resolution of seizures in our patient. The selectivity of topiramate is noteworthy, as when the patient suspended the treatment for 1 week, seizures recurred, with rapid cessation after restart of the antiepileptic drug. Nonetheless, one should be cautious in the interpretation of this observation, as stopping any AED on which a patient's seizures are well controlled could lead to the resurgence of seizures and/or status epilepticus.

From the immunotherapy point of view, the early response of clinical rheumatological signs (skin and joint involvement) and normalization of serological markers, associated with the persistence of high titer anti-P and stable abnormalities observed in follow-up MRI, difficult the assessment of the patient's SLE treatment. As her epilepsy successfully respond to topiramate, no changes in her immunotherapy regimen were proposed. Nonetheless, high dose intravenous methylprednisolone, immunoglobulins or plasma exchange, could also have been suitable options for treating her refractory autoimmune epilepsy, possibly reducing circulating antibodies.

Perhaps, seizure relapse will be the only clinical indicator of reactivation of her SLE. According to the 2019 recommendations, mycophenolate should be avoided, while aggressive treatment with cyclophosphamide or off-label rituximab may be considered in case of breakthrough disease (Fanouriakis et al., 2019).

Finally, it is important to note that seizures are common among SLE patients, not only as a neuro-SLE manifestation but even as a complication of systemic compromise (e.g. acute electrolyte disturbances, renal failure, posterior reversible encephalopathy syndrome, etc.) so, although phenytoin and other antiepileptic drugs such as carbamazepine and lamotrigine have been associated with drug-induced lupus and are unlikely to affect SLE disease course, chronic use may provoke uncertainty in determining SLE stability, and treatment schedules should be carefully chosen in each patient (Chang and Cole, 2014).

4. Conclusion

The approach to patients with drug-resistant focal epilepsy, defined as the correct use of two antiepileptic drugs (as monotherapy or combination therapy) with no resolution of seizures (Kwan et al., 2010), has been centred in the surgical resection of the probable epileptogenic zone. However, the understanding of the underlying pathophysiological mechanisms involved in the individual patient can allow the establishment of the most appropriate therapeutic intervention, aiming for more personalized and precise medicine in the near future (Kearney et al., 2019). This case report provides a plausible link between the patient's anti-P antibodies and refractory epilepsy due to response to topiramate but would require further investigation in a bigger cohort of patients.
